This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

LITTLE, we believe, need be said of the advantages of the rapid dissemination of scientific information, and that little has been so well said by a great scientific authority, that we make no apology for quoting here from a work so well known as Sir JOHN HERSCHEL'S *Preliminary Discourse on the Study of Natural Philosophy.*

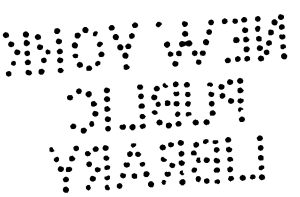
"Perhaps it may be truly remarked," says that distinguished man, "that, next to the establishment of institutions having either the promotion of science in general, or, what is still more practically efficacious in its present advanced state, that of particular departments of physical inquiry for their express objects, nothing has exercised so powerful an influence on the progress of modern science as the publication of scientific journals, of which there is now scarcely a nation in Europe which does not produce several. The quick and universal circulation of these, places observers in all countries on the same level of perfect intimacy with each others objects and methods, and serves to direct the course of general observation, as well as to hold out in the most conspicuous manner models for emulative imitation. Nothing can be more discouraging to one engaged in active research than the impression that all he is doing may, very likely, be labour taken in vain; that it may, perhaps, have been already done, and much better done than with his opportunities or his resources he can hope to perform it; and on the other hand nothing can be more exciting than the contrary impression. Thus by giving a connected view of what has been done, and what remains to be accomplished, those digests and bodies of science which from time to time appear have, in fact, a very important weight in determining its future progress, quite independent of the quantity of information they communicate."

What was so true in 1830 is still more so in 1860, for in these thirty years what progress has Chemistry made! In 1830 one moderately sized octavo volume contained all that was known of the science, and the names of the observers were comparatively few. To day a "Handbook" of Chemistry already extends to thirteen volumes, and is still uncompleted, while the name of the experimenters is "Legion." From this cause the continual additions made to our knowledge of the science renders a special work on the subject out of date almost as soon as printed. It was to supply the English Chemist with these constant extensions that the CHEMICAL NEWS was first projected, and it is confidently hoped that the design has been in a great measure fulfilled. That the attempt has been well received is sufficiently shown by the circulation and influence the Journal has already attained, and which is still extending.

In looking back over the contents of this volume the Editor sees much on which to congratulate himself and his readers. It is no small honour to a Journal to have been the means of preserving the interesting Lectures of FARADAY,— which, dealing with the elements of science, command the admiration of the learned as well as excite the interest of the student. To record the valuable experience of practical analysts like Messrs. FIELD and SUTTON, and the interesting researches of Messrs. WILLIAMS and CHURCH, cannot fail to have been useful: to these gentlemen, and many others, we have to offer our sincere thanks.

Nor should we omit to confess deep obligations to the various Foreign Scientific Journals from which, as our readers know, we abstract and quote liberally. It has therefore afforded us much pleasure to see that our continental *confrères* have as freely availed themselves of the original matter contributed to the CHEMICAL NEWS. The papers of Messrs. WILLIAMS, CHURCH, SPILLER, SUTTON, FIELD, BARRATT, ATTFIELD and others have been republished in several of the Chemical Journals of Germany and France, and so become permanent additions to the stock of European knowledge.

June, 1860.



THE CHEMICAL NEWS.

Vol. I. No. 1. — December 10, 1859.

INTRODUCTORY ADDRESS.

The diffusion of facts which may tend to improve and augment our knowledge of the arts and sciences upon which most of the operations of civilised life are based, must ever be a pleasing task to those who hold in esteem the welfare of mankind. It is with this feeling that the CHEMICAL NEWS is introduced to the world.

Chemical Science during the last quarter of a century has made such extended progress that our arts and manufactures assume altogether a different aspect. Those chemical arts which formerly were rudely conducted by the system termed the "rule of thumb," are now methodically organised and arranged in accordance with the unerring laws of chemistry, and the theoretical principles upon which each art is based, as well as its practice, now receive due attention from the more enlightened chemical manufacturer. Hence, not only are more accurate and uniform results obtained, but success and economy take the place of failure and waste. The general diffusion of scientific knowledge has done much to accomplish this desirable end; and to the scientific institutions and the press are due the credit of this great reformation.

The scientific journalists in this country,—availing themselves of the vast amount of discovery and improvement which has been from time to time freely given to the world by the Continental chemists in their numerous publications,—have duly recorded in our own language the results of the labours of our foreign scientific brethren; and thus some of the most useful and valuable arts which have ever been discovered by man, have, during the past twenty years, become universally spread over the globe; whereas, had it not been for the British Scientific Press, many of these valuable discoveries would have failed to receive that popularity or generalisation which extends their usefulness to all mankind, instead of merely benefiting the few. For it must be admitted that the general adoption of any well-tried process in Great Britain goes far to insure its application over the greater part of the civilised world.

At the present time, however,—remarkable though it may seem,—there is no WEEKLY JOURNAL in England which has for its aim the publication of those scientific processes and discoveries, the knowledge of which tends so greatly to increase our importance as a nation devoted to improvement, refinement, and industrial excellence. It is therefore to supply this deficiency that the CHEMICAL NEWS is now launched into the stream of scientific literature.

After a lengthened and careful deliberation upon the plan which it would be best to pursue; the present form and arrangement of subjects has been adopted in order to meet the views of all persons interested in scientific matters, either as chemical manufacturers, pharmaceutists, or amateur experimentalists, &c., and it is earnestly hoped that it may meet with that approval and support which it will ever be the desire of the Editor to ensure, based upon the solid foundations of merit and careful attention.

Each number will be divided into several sections, which will have a *general* but no *individual* connection with each other. We shall commence with SCIENTIFIC AND ANALYTICAL CHEMISTRY, under which head will be given the results of elaborate investigations in the laboratory, by those pioneers of our science who by their labours pave the way for the subjects treated of in our second department,—TECHNICAL CHEMISTRY. Here will be described the practical applications of the processes, formulæ, or chemical agents, which the labours of the purely scientific chemist have placed at the disposal of the manufacturer. In the department of Agricultural Chemistry especial care will be taken to place before the agriculturists of the United Kingdom all the most interesting and useful information to be derived from Home or Continental sources, or from the States of America.

PHARMACY, TOXICOLOGY, &c. next follow, and the Medical Profession will here find from time to time everything of interest relating to Pharmacy, Materia Medica, and Toxicology. Discussions upon Medical Reform and Jurisprudence will also be freely admitted into these columns.

In inviting the support also of the important body of Chemists and Druggists, we offer them our strongest assurance that whatever information may be deemed useful to them, or to their apprentices and assistants, will be duly recorded from week to week; at the same time the Journal will be open to all useful discussions bearing upon their interests and canvassing their grievances, and in this respect it is hoped that the CHEMICAL NEWS will be looked upon as the especial organ of the extensive and important body of Pharmaceutists.

THE PROCEEDINGS OF THE VARIOUS LEARNED SOCIETIES in which the readers of the CHEMICAL NEWS may be supposed to take particular interest, such as the Chemical and Pharmaceutical Societies, will next be given; which will be followed by NOTICES OF BOOKS, PATENTS, &c. under which head will appear impartial criticisms of the more important works of a scientific

or technical character, and abstracts of recent chemical patents.

The Correspondence department will be of a more general character; and, as far as space will permit, this part of our Journal will be freely open for the discussion of all matters relating to any subject of general or particular scientific interest. It must however be borne in mind that a scientific journal is not the proper medium for discussions which overstep the bounds of calm philosophical reasoning; and therefore all personalities will be rigidly excluded. Under this heading will also appear *Chemical Notices from Foreign Sources*, in which either a full or brief abstract will be given of all important chemical papers published abroad. It will be our object to render this branch as complete as possible, so that the careful reader of the Chemical News may really be kept *au courant* with the progress of continental research.

The next departments, viz. Scientific Notes and Queries and Laboratory Memoranda, cannot fail to become of the greatest value to many who may desire to overcome difficulties or elucidate facts for the benefit of themselves and their fellow-labourers in the field of Science; for it cannot fail to have been remarked how vast a number of interesting facts of daily occurrence in a laboratory of research are lost to the world, owing to the want of a readily accessible medium of intercommunication, in which such *Laboratory Notes* could find a convenient record. This department will therefore contain observations and inquiries relating to all branches of Chemical Science; and by thus offering students and practical men facilities for the interchange of their ideas and the communication of improvements and discoveries, the Chemical News will necessarily become a most important stimulus to the diffusion and advancement of scientific knowledge.

In the section following—Miscellaneous—will be given such notices, abstracts, or quotations from our contemporaries or other sources, as do not properly belong to any of the above departments; and under the concluding heading will be given Answers to Correspondents. In this branch great care will be taken to reply to correspondents who may require information upon any subject within the province of this Journal, and they are invited to look upon the Chemical News as a most willing monitor.

The Chemical News will be especially valuable when bound and kept in a convenient position amongst other scientific works of reference. Its value will therefore depend in some measure upon the accuracy and copiousness of its Index, and particular attention will consequently be paid to render it as complete as possible in this respect.

We have now sketched our programme. Each section has been the subject of careful consideration; and the different departments have been arranged with a view to present such a variety as might be thought likely to give the greatest satisfaction to our readers; at the same time we do not pledge ourselves to a strict adherence to any of the above sections; it is very possible that the experience of a few months may show that modifications either in addition or curtailment are desirable, and it would therefore be unwise to bind ourselves to an inflexible rule of action. The editorial staff of writers and contributors is of the most varied and talented description, and it will be the constant endeavour of every one connected with this Journal to render it both truly and honestly deserving of the title under which it is now ushered into the world—The Chemical News.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On Vapour Volume, by C. Greville Williams.

Of all the questions now argued among chemists, there is none of more paramount importance for the development of theory than that of vapour volume. It has been common to consider three degrees of condensation as obtaining among chemical substances, namely, to one, two, or four volumes. As an illustration of the first, may be mentioned oxygen, atomic weight = 8: of the second, hydrogen = 1, and of the third, olefiant gas = C_4H_4. But it is plain as regards these relations there is no absolute datum to start from—no unchangeable law of nature round which, as a centre, all our ideas of vapour volume must rotate. Thus the advocates of the unitary system, by raising the atomic weight of oxygen to 16, double its volume, and consider it, in the state of vapour, to occupy the same space as hydrogen. Nevertheless, disregarding, for the purpose of this discussion, the question of the vapour volumes of the elements, a question which can without much difficulty be answered for all practical purposes by the advocates of either system, we go at once to the point by asking, "Is there any amount of gaseous condensation which must be regarded as universally obtaining with organic and inorganic compounds?" In our illustrations we shall use the old notation, not that by so doing we wish to imply a belief in its being more correct than the numbers adopted in the unitary notation, but simply because it is submitted that, as no final argument, no crucial experiment can be brought to bear with overwhelming force upon the side of either theory, it were safer to adhere to the old until further researches have shown its fallacy.

The questions at issue resolve themselves into two, namely:—

1. "Do all compounds undergo a condensation to four volumes?"

2. "Can one atom of a substance contain one equivalent of oxygen = 8?"

Chemists have been, for half a century, reproached with a violent tendency to dogmatise upon doubtful points. They have also been reproached with the circumstance, that not only since chemistry has been a science have there always been two or more theories contending for the mastery,—but, which is far worse, the rival theories are often equally balanced in the scales of argument, and, still oftener, rival theories are discovered to be capable of reigning harmoniously together. As an instance, let us remember the theories of radicals, substitutions and types.

It somewhat unfortunately happens that in answering the above two questions, it is not indifferent which we begin with! for if we decide that all compounds condense to four volumes, and four volumes only, then we are constrained to admit that an equivalent of oxygen = 8, may exist in one atom of a substance, and consequently, that the lower atomic weight must be received. If, on the other hand, we assert that one atom of a substance cannot contain one atom = 8 of oxygen, then we must admit of eight volume formulæ.

But it will be more profitable to see what bearing facts have upon the questions at issue.

In the first place numerous substances have been investigated which have only half the density which would be expected in the event of their condensing to four volumes. It would appear, therefore, that they

possess eight volume formulæ. Among them some of the most prominent and best ascertained are perhaps the following.

Substance.	Density of Vapour.		
	Experiment.	Theory, 4 Volumes.	Theory, 8 Volumes.
Sal ammoniac . . .	0·890	1·850	0·925
Pentachloride of phosphorus	3·654	7·214	3·624
Hydrosulphate of sulphide of ammonium . . .	0·884	1·765	0·882
Hydrotellurate of telluride of ammonium . . .	1·320	2·840	1·420
Hofmann's new base . .	2·260	4·620	2·310
Tetrethylammonium iodide.	. .	8·890	4·445

It is unnecessary to add more examples, because the above contain all the features requisite to enable us to discuss the cause of bodies only condensing to eight instead of four volumes.

Most of the substances mentioned above may be considered to undergo decomposition at the elevated temperature at which the experiment is made, the result being that the balloon, instead of containing one vapour of anomalous expansion, contains *two vapours*, each asserting its individuality as a four volume gas. As soon, however, as the balloon cools, the two gases unite to reproduce the original substance. Thus we may assume the following diagrams to represent the contents of the balloons at the temperature of vaporisation.

I.

NH_3= 4 vols.	HCl= 4 vols.

8 vols. of NH_4Cl.

II.

PCl_5= 4 vols.	Cl_2= 4 vols.

8 vols. of PCl_5.

III.

NH_3= 4 vols.	2 HS= 4 vols.

8 vols. of NH_4S, HS.

IV.

NH_3= 4 vols.	2 TeH= 4 vols.

8 vols of NH_4Te, TeH.

V.

$C_{12}H_{16}N_2$= 4 vols.	2 HO= 4 vols.

8 vols. of new base.

VI.

$C_{12}H_{13}N$= 4 vols.	CH_3I= 4 vols.

8 vols. of iodide of tetrethylammoninm.

Whatever may be the true nature of the phenomena in the third and fourth cases, it is certain that bodies sometimes break up in the heated balloon in the manner indicated, and on cooling regain their former condition. For example, Hofmann has found that the iodide of tetrethylammonium breaks up when heated into four volumes of triethylamine and four volumes of iodide of ethyle, but, on cooling, the two bodies re-unite to form the original compound. In proof of this it may be mentioned that if the iodide of the ammonium base be distilled *into water*, the triethylamine dissolves and the iodide of ethyle settles to the bottom. Reactions will one day appear, proving the nature of the decompositions which take place with the other examples given. In fact the dioxide of Hofmann's new diammonium base splits up under certain conditions which indicate that 8 volumes of its vapour certainly consist of four volumes of an alkaloid plus four volumes of water vapour.

The above illustrations suffice to show that both in organic and inorganic chemistry substances exist which in the state of vapour occupy twice the volume of the majority of bodies. But, on the other hand, what shall we say where the compounds for the same metal occupy two volumes in one, and four volumes in the other class of salts? This actually happens with the chlorides and bromides of mercury, as will be seen from the following table.

Substance.	Density of Vapour.		
	Experiment.	Calc. 4 Volumes.	Calc. 2 Volumes.
Mercuric iodide, HgI. . .	15·90	. .	15·708
Mercuric bromide, HgBr. .	2·16	. .	12·456
Mercuric chloride, HgCl. .	9·80	. .	9·377
Mercurous bromide, Hg_2Br.	10·14	9·68	
Mercurous chloride, Hg_2Cl.	8·35	8·14	

From the above results we are forced to admit that in mercuric and mercurious salts the vapour volume is just that of the metal or chlorine, &c. and the vapour volume of one of the elements becomes altogether lost. It would perhaps be a violent inference to conclude the true atomic weight of the metal to be 200 = 4 volumes. This, however, would have the effect of giving all these salts of mercury the same condensation, namely to four volumes. We should then of course have to use the old nomenclature and say biniodide, bichloride of mercury, &c. It is probable that the convenience of removing the above substances from the anomalous position of having two vapour volumes, would be at least as great as the inconvenience of giving a metal a 4 volume equivalent.

The chlorides of bismuth, antimony, and arsenic give 4 volume; and the chlorides of tin, titanium, and silicon 2 volume formula. But then, if the same rule holds here that we have seen with the compounds of mercury, we might say that this is because the former are *ous* salts, whereas the latter are fully saturated with chlorine. As regards bismuth, we do not know of a higher chloride that $BiCl_3$; whereas with antimony and arsenic, we know that compounds with five atoms of the electronegative body exist. Their vapour densities have not, however, been determined. Probably they will decompose in the manner we imagine pentachloride of phosphorus to do, the result of course being an augmentation of volume.

From what has been said, it is evident that, however we may desire to find a universal unit of volume for compound gases, either organic or inorganic, it is impossible to lay down any law until further researches have been made. One set of reactions are often in favour of certain views, while another of no less importance appear to force us to diametrically opposite conclusions. As one example among many, let us cite the controversy respecting the atomic weight of silicon, the vapour densities of the chloride and fluoride leading to one formula, while the difference between the boiling points of the chloride and bromide points to another. With regard to the second question, we shall be very brief. If it can be shown that four volumes of any substance (and four volumes representing an equivalent) contain one equivalent (= 8 parts) of oxygen, then all the theories which, under the name of the unitary system, have been built upon the foundation of O, having an atomic weight of 16, will fall. Nevertheless, Bruning has obtained a substance by acting on iodoform with potash, which certainly appears to contain C_2HI_2O = 4 vols. Experiment gives for the vapour density 9·55. Theory requires 9·515. As it is probable that some other chemists have discovered bodies having one equivalent of oxygen for four volumes of vapour, but have rejected their experiment from fear of appearing heterodox, it is hoped that such experiments may be brought to light, with a view of discussing their merits.

The above has been written with the hope of calling the attention of those chemists who have hitherto neglected the subject of vapour volume to the importance

of accumulating and publishing data from which conclusions can be drawn.

Before ending this notice, it is desired to put into the hands of students the following excessively simple and easy method of calculating vapour densities from atomic weights. It is the shortest that can possibly be used, as it only requires one multiplication; moreover, the results are perfectly accurate, as they solely depend on the density of hydrogen, a datum which has been determined with extreme precision.

To obtain the density of a vapour or gas having a *one* volume formula, such as oxygen (equiv. 8); multiply the atomic weight of the gas or vapour by twice the density of hydrogen = 0·1384.

If a *two* volume formula, multiply by the density of hydrogen = 0·0692.

If a four volume formula, multiply by half the density of hydrogen = 0·0346.

If an eight volume formula (*e.g.* PCl_5), multiply by one quarter the density of hydrogen = 0·0173.

It is evident that, in order to obtain the atomic weight from the vapour density, it is only necessary to divide the latter by the density of hydrogen, or a multiple or sub-multiple of it, according as we have a one, two, four, or eight volume formula to deal with.

On a New Process for preparing certain Chlorinated Derivatives of the Benzole Series, by ARTHUR H. CHURCH, *F.S.C.*

MONOCHLORINATED benzole, or chloride of phenyle $C_{12}H_5, Cl$, has been obtained by the action of pentachloride of phosphorus on hydrate of phenyle; while the next term of the series, chloride of toluenyle, $C_{14}H_7, Cl$, is formed when toluole is distilled in a stream of chlorine. The higher homologues of these bodies have not been obtained as yet; and while both the methods mentioned above are somewhat uncertain in their results, the latter process is not applicable in all cases. A new plan of procedure was therefore much to be desired, and that which I have now to mention seems, so far as I have tried it, to promise the best results: and I think it is applicable to hydrocarbons other than the homologues of benzole, to olefiant gas, for instance.

Finely powdered bichromate of potassium is to be introduced into a flask, together with sufficient water to moisten the salt; considerable excess of hydrochloric acid is then to be poured in. The flask must be placed in a sand-bath, and heated till a slight evolution of chlorine occurs; the hydrocarbon is now poured upon the surface of the mixture, while a perforated cork, in which a long piece of combustion-tube has been mounted, is inserted in the neck of the vessel to serve as a condenser for the hydrocarbon. The green colour of the chlorine is never visible, for the hydrocarbon absorbs every trace. The chromic solution is rapidly reduced, and the process is generally complete after a few hours heating of the mixture at a gentle heat. The hydrocarbon becomes less and less volatile, and also less and less mobile, until none of it remains unacted upon. The mixture is now allowed to cool, and the oily layer on the surface removed by the pipette. After having been washed with hydrochloric acid, with aqueous potash, and with water, it may be dried by means of chloride of calcium, and then heated to separate any traces of the original hydrocarbon. The chlorides of phenyle and toluenyle may be distilled without change; the chlorides of xylenyle and cymenyle, which I have prepared in some quantity, suffer decomposition when heated beyond 200° C. The chloride of xylenyle is an aromatic oil of pleasant odour (it was made with pure xylole from coal naphtha), and it boils at about 216° or 218°; but at this temperature it already begins to evolve hydrochloric acid. Unlike the original hydrocarbons, all these chlorides are considerably heavier than water, but they float upon a saturated solution of common salt. A rough experiment gave 1·135 as the specific gravity of chloride of xylenyle, while that of the chloride of cymenyle is nearly 1·146; these numbers are probably a little too high.

Now that these chlorides may be easily obtained in any quantity, I intend to study their reactions and transformations in detail. I have already prepared the cyanide of xylenyle by the action of cyanide of potassium upon the chloride. The cyanide is a disagreeably-smelling oil heavier than water, which, when heated with an alcoholic solution of potash, yields ammonia, and the potassium salt of an organic acid, probably a new acid, the xyloic: the reaction may be thus expressed:—

$$\underbrace{C_{10}H_9, C_2N}_{\text{cyanide of xylenyle.}} + KO, HO + 2\,HO = \underbrace{C_{18}H_9KO_4}_{\text{xylate of potassium.}} + NH_3$$

The action of hydrate of potassium in this transformation is very slow; even after several hours digestion much of the organic cyanide remains undecomposed. Cannizarro has already obtained toluic acid by a precisely analogous transformation. The chloride of cymenyle should yield cyminic acid, $C_{22}H_{14}O_4$, in the same way. When this chloride is distilled with dry carbonate of ammonium, it yields an oily organic base, presenting all the characteristics of cymidine.

In giving this slight sketch of a process by which the proto-chlorides of certain organic radicals may be obtained, I reserve further details for a second communication. There is one point, however, of some interest connected with these experiments that it may be well to mention here. If the hydrocarbon to be chlorinated be poured upon the chlorine mixture before the evolution of chlorine has actually commenced, considerable quantities of oxidised acid products are obtained. In this way xylole yields, among other compounds, toluic acid, while with cymole cuminic acid is formed.

Lincoln College, Oxford, Dec. 6th, 1859.

On the Separation of the Oxides of Nickel and Cobalt from Peroxide of Iron, by FREDERICK FIELD.

IN the year 1857, I published a short paper in the *Chemical Gazette* on the separation of oxide of manganese from oxide of iron by means of oxide of lead. It was remarked, that although the separation was satisfactory, sulphuretted hydrogen had to be employed to precipitate small quantities of lead from the manganese solution, even after the addition of sulphate of soda. Subsequent experiments have proved, however, that if dilute sulphuric acid be used there is no difficulty of the kind, and the oxide of manganese can at once be precipitated by potash. The same is the case with the precipitated peroxide of iron and the excess of oxide of lead. When these precipitates are digested in weak nitric acid and sulphuric acid, or a soluble sulphate added, it can easily be supposed that the whole of the lead is not thrown down; but if they are digested in dilute sulphuric acid, no lead can be detected in the solution of the persulphate of iron. It is necessary to avoid as much as possible the presence of hydrochloric acid, as that body, as is well-

known, decomposes sulphate of lead. The separation of oxide of cobalt, or oxide of nickel, from oxide of iron, can be determined with equal facility by the same method.

In the case of nickel and iron, the nitrates are evaporated nearly to dryness, and after the addition of water, oxide of lead (litharge) is added, and the whole boiled for ten minutes or a quarter of an hour. The iron is entirely precipitated, the nitrates of nickel and lead remaining in solution. After filtration, which can be effected with great readiness, dilute sulphuric acid is added, and on standing for sixteen hours, the sulphate of lead is filtered off, and the nickel precipitated and estimated in the usual manner.

The filter containing the peroxide and excess of litharge is digested in dilute sulphuric acid, filtered and washed. The filtrate is precipitated by potash.

10·00 grains of pure iron dissolved with 5·00 grains of nickel gave 14·22 Fe_2O_3 and 6·41 NiO. (Calculated 14·29 Fe_2O_3 and 6·43 NiO.)

5·00 grains iron and 10·00 grains nikel gave 7·12 Fe_2O_3 and 12·81 NiO. (Calculated 7·145 Fe_2O_3 and 12·86 NiO.)

It may here be remarked that oxide of nickel can be more readily determined by precipitation as *peroxide*, by means of hypochlorite of soda than as oxide by caustic potash. Peroxide of nickel, after boiling the solution in which it is suspended, separates as a rather dense precipitate, and can be easily washed, whilst the great difficulty of freeing the potash from the bulky gelatinous protoxide is well known. The alkali, indeed, adheres with remarkable pertinacity to this substance, and if not added with considerable caution, and other circumstances attended to, very protracted washing is necessary.

In employing the hypochlorite of soda, it is requisite to have an open vessel, a beaker for instance, as the peroxide is liable to form flakes upon the sides of the glass, which are difficult to remove from a narrow-necked flask. The peroxide is heated to whiteness, and the nickel weighed as protoxide.

Cobalt can be separated from iron in precisely the same manner as nickel. Many analyses have shown that no trace of cobalt is precipitated from its solution on boiling with oxide of lead, and even when the iron is in considerable excess, 50 to 1 for example, the separation is complete.

The solution of cobalt freed in this manner from iron, contains no trace of that metal, gives no shade of blue with ferrocyanide of potassium, nor can iron be recognised by any known test.

In conclusion, the separation of the oxides of nickel and cobalt from iron can be effected with equal accuracy by oxide of lead, as by carbonate of baryta, and the operation is speedier, as a few minutes brisk ebullition is sufficient. The oxide of lead, with ordinary care, can be removed as easily from the solution as the baryta, by means of sulphuric acid.

TECHNICAL CHEMISTRY.

On Platinum and its associated Metals, by MM. Deville *and* H. Debray.

The *Annales de Chimie et de Physique* for August last contains a very elaborate article by the above chemists on the subject of platinum and the metals which accompany it. The results at which they have arrived are so important, and they are moreover of such interest, that we are induced to lay before our readers a few of the principal facts contained in their memoir.

The metallurgy of platinum is altogether a modern art, the introduction of the metal into the laboratories of science and industry dating but from a few years back; and although particularly deserving the attention of the chemist, the metallurgy of platinum and its congeners is, in general, but little known. Except for chemical purposes, platinum has not hitherto received any important application; but when we know better where to look for its ores, and when the deposits already known are more extensively worked, the ores of platinum will, perhaps, become no rarer than gold; and as the metal is almost indestructible, and as its value protects it from losses and accidents of all kinds, it must in time accumulate and thus become more plentiful. It may then perhaps be applied to other useful purposes in which its weight and slightly tarnished colour will be no objection, or for which its absolute unalterability will give it a peculiar value. The solution of these questions, however, depends on the price for which the metal can be supplied; and the chemist is particularly interested in seeing its cost so far reduced that the large vessels of the laboratory may be made of platinum. It was in the hope of facilitating a progress of this kind, that MM. Deville and Debray undertook the difficult researches the results of which are given in the above-mentioned memoir, a work which has cost them more than four years of labour.

Until the first communications of M. Deville were published no one dreamt of utilising all the metals found with platinum, and with the exception of palladium and osmium, which there was always a motive for separating, platinum alone has been extracted from the ores, leaving a residue which has accumulated in all the manufactories in Europe as well as in the Russian Mint.

The processes described are exclusively by the dry way, and by fusion at a very high temperature. They are given in different chapters, which treat of "the revivification of pure platinum," "the metallurgy of pure platinum," "the extraction from the rough ore of a triple alloy of platinum, rhodium, and iridium of a suitable and invariable composition;" and lastly, the extraction, whether from the residues or from the osmide of iridium, of the utilisable metals, platinum, paladium, rhodium and iridium.

We give first, the methods practised for obtaining pure platinum, reserving for a future occasion the interesting accounts of the individual metals, and the methods for essaying the rough ores and residues.

In commerce, platinum is found which is almost free from iridium, but which still contains traces of osmium and a little silicium. MM. Deville and Debray have discovered that fusion in lime by means of an oxidising flame, refines it perfectly, osmic acid being disengaged, and the silicium becoming converted into silicate of lime, which melts into a colourless bead, and moves rapidly about on the surface of the metal until it reaches the edge, where it is absorbed by the sides of the furnace. Platinum so melted and refined is a metal as *soft* as copper; it is whiter than ordinary platinum, and does not possess the porosity which has hitherto been an obstacle to the manufacture of an impermeable platinum sheath.

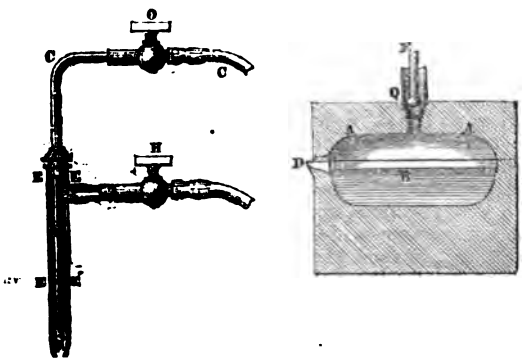
Melted platinum still possesses the property of condensing gases at its surface, and of producing the phenomenon of a lamp without flame. Its density = 21·15—less than the density of ordinary platinum which has been subjected in the working to a powerful hammering (*d'un écrouissage extrêmement énergique*).

We now proceed to describe the apparatus by means of which platinum has been melted, in quantities relatively

considerable, and run into ingots, like a metal of ordinary fusibility.

The fuel most often employed has been common coal-gas, but hydrogen may be used, and when pure will give even a greater heat. The combustion is fed by a current of oxygen. The furnace in which the fusion is made, is of lime bound with iron wire. It is composed of two parts: 1. the roof A A, made of a cylindrical piece of lime slightly arched on its lower surface, and pierced by a conical hole O, through which a blowpipe C E is to pass: and 2. a bottom B, made of another piece of lime, hollowed as shown in the diagram. The hollow should be scooped out so deep, that the melted platinum may occupy a depth of 3 or 4 millimetres or more. At the anterior part D, a groove inclined a little towards the inside is made with a file, which is to serve as a hole for the metal to run out of and for the flame to issue from.

The blowpipe is composed of a copper cylinder E E, terminated at its lower extremity by a slightly conical



tube E′ E′, made of platinum. A copper tube C C C, having a platinum nozzle, enters the first cylinder at its upper extremity, and is so arranged as to allow the nozzle to be slid up or down, and placed at any height from the lower end of the cylinder E E E′ E′, that may be wished.

A stopcock H, is attached to the side of the cylinder F, by means of a tube as large as the cylinder itself. Another stopcock O, terminates the elbow of the tube C. It is by the stopcock H, that the hydrogen or coal gas passes, and the oxygen is introduced through the stopcock O.

When the fusion is to be made, the pieces of lime composing the furnace are put together in the way represented in the diagram. Then, holding the blowpipe in the hand, the stopcock H is opened so as to allow the passage of a gentle stream of gas which is lighted, and the stopcock O is turned to admit the oxygen necessary for the combustion. The flame is in this way plunged into the apparatus by the hole O, in such a manner as to avoid an explosion, which might disturb the pieces of lime. The body of the furnace is now gradually heated; the quantity of the gases passing being increased by degrees until the maximum temperature is attained. The degree of heat may be raised or lowered as need be, by raising or lowering the platinum nozzle which supplies the oxygen. The temperature is now lowered, and the platinum is introduced, by little and little, through the opening D. When it is in thin slips of less than a millimetre in thickness there is scarcely time to introduce them. They are seen to melt and disappear almost at the moment they enter the furnace. The oxygen should arrive at a regular pressure of about four or five centimetres of mercury, and ought to give a rotatory movement to the platinum so as to equalise the temperature throughout the mass.

When it is not wished to run the metal into a mould, the fusion being perfect, and the refining completed, which is the case when no more vitreous matter is seen to form on the surface, the two gases are turned off by degrees, always leaving the oxygen in a decided but very slight excess. The mass now gradually solidifies, and the flame may be completely extinguished. A little of the metal is always thrown up to the roof of the furnace, where it may be easily collected after the operation is finished.

When the platinum is to be cast, an ingot mould is prepared of thick cast iron, well rubbed with plumbago, or of coke or lime. The last are most easily made of plates of the substance, sawn, and held together by iron wire. The roof of the furnace is taken off, the body seized with a pair of tongs, and the platinum is poured out, without hurrying, just as we should any other metal. The only difficulty which occurs, and this a little practice will enable the operator to overcome, is to discern at the same time the dazzling surface of the metal and open mouth of the mould, before turning up the crucible. A larger quantity than 3 or 4 kilogrammes should never be cast in this way, inasmuch as there would be great danger of some part of the apparatus giving way.

For greater quantities, the authors describe how a larger furnace may be made of several pieces of lime bound firmly together with iron; and an ingenious and simple arrangement, by means of which the metal may be poured out without taking up the bottom part of the apparatus. The reasons they give for preferring to use lime in the construction of the furnace are as follows:—

1. Lime is perhaps the worst conductor of heat known; so much so, that through a thickness of at most 2 centimetres (0·8 inch), the apparatus being full of melted platinum, the temperature of the outside is barely 120° (Cent.).

2. Lime radiates heat most perfectly. For this reason it is the best material for the sides of a reverberatory furnace of this kind.

3. Lime acts on all the impurities from which we wish to free platinum — iron, copper, silicium, &c. changing them into fusible compounds which are absorbed by its porous substance. It acts like a cupel, the material purifying the metal melted in it.

An experiment made in the laboratory of the *Ecole Normale* showed that the quantity of oxygen required to melt 1 kilogramme (2·2 lbs. Avoird.) of platinum was only 60 litres (about 13 gallons), the cost of which was estimated at 0·4 of a franc. The cost of the coal gas or hydrogen used was not considered worth taking into account.

The process applied to the revivification of old platinum gives excellent results. No foreign metal except iridium and rhodium can exist in platinum after it has been melted and refined in the method described. All the substances which most easily attack platinum, sulphur, phosphorus, arsenic, gold, soda, iron, copper, palladium, and osminum, are separated either by oxidation and absorption by the lime or by volatilisation. Gold and palladium escape in the form of vapour, and may be easily collected by making the flame which issues from the furnace pass through an earthenware tube, in which will be deposited all the volatile matters except the osmic acid, which may be condensed if the vapour is made to pass over a vessel full of ammonia. A part of the osmium is also deposited in the tube in a metallic state.

The only caution to be observed in the process is never to have the bath of metal of more than 4 or 5 centi-

metres thickness without keeping it in constant agitation; because the platinum is too bad a conductor to remain perfectly liquid if it is in greater depth; and, therefore, there will be a chance of the refining not being complete, or of the perfect fusion of the mass not being quite effected.

On the Employment of Carbon as a means of Permanent Record, by John Spiller, *F.C.S., of the War Department.*

The undoubted superiority, in respect to the quality of permanence, of ordinary printed characters in comparison with the several kinds of manuscript, renders it desirable that efforts should be directed to the possibility of availing ourselves of the unalterable nature of carbon, the principal ingredient in printer's ink, with a view to the employment of the same as a substitute for the tannate of iron in the ordinary black writing fluids. The want of permanence constantly attributed to the latter, and borne out by the inspection of manuscript deeds of comparatively recent date, seems inherent to an ink which depends solely for its permanence on a weak chemical affinity exerted between the oxides of iron and the product of a vegetable infusion, which, left to itself, is constantly undergoing change. Hence the application of dilute acids, both mineral and organic, is sufficient either to obliterate or render illegible the characters written with such ink; while its composition makes it liable to fade under circumstances no more unfavourable than that of exposure to a damp or impure atmosphere.

On the other hand, the imperishable nature of carbon, in its various forms of lamp black, ivory black, wood charcoal, and graphite or black lead, holds out much greater promise of being usefully employed in the manufacture of a permanent writing material; since, for this substance, in its elementary condition, and at ordinary temperatures, there exists no solvent nor chemical reagent capable of effecting its alteration. Carbon is destroyed, or rather oxidised, only by fire, and by the long continued action of the strongest acids; only under such circumstances, therefore, as the tablet of prepared vegetable or animal substance is itself unable to withstand. Provided, then, that sufficient means can be adopted for securing its perfect adhesion to the surface, or passage even into the pores, of the paper (a point not sufficiently considered, perhaps, in the production of the so-called permanent carbon photographs), there seems every probability of a carbon pigment resisting the effects of time and other corrosive influences better perhaps than any other substance, elementary or compound, which is likely to be brought into comparison with it. The perfect state of preservation of the early engravings and pages of printed type corroborates this view; they exhibit in some instances evidence of destruction by decay of the paper itself, rather than that of the carbonaceous material forming the subject of the picture.

The suggestion relative to the mode of applying carbon to these purposes, which it is intended more particularly now to enunciate, depends on the fact of the separation of carbon from organic compounds, rich in that element, sugar, gum, &c. by the combined operation of heat and of chemical reagents, such as sulphuric and phosphoric acids, which exert a decomposing action in the same direction; and by such means to effect the deposition of the carbon within the pores of the paper by a process of development to be performed after the fluid writing ink has been to a certain extent absorbed into its substance. A system of formation by which a considerable amount of resistance, both to chemical and external influences, appears to be secured. An ink of the following composition has been made the subject of experiment:—

Concentrated sulphuric acid, deeply coloured with indigo . . .	1 fluid ounce.
Water	6 „ „
Loaf sugar	1 ounce troy.
Strong mucilage of gum arabic .	2 to 3 fluid ounces.

Writing traced with a quill or gold pen dipped in this ink dries to a pale blue colour, but if now a heated iron be passed over its surface, or the page of manuscript held near a fire, the writing will quickly assume a jet black appearance, resulting from the carbonisation of the sugar by the warm acid, and will have become so firmly engrafted into the substance of the paper as to oppose considerable difficulty to its removal or erasure by the knife. On account of the depth to which the written characters usually penetrate, the sheets of paper selected for use should be of the thickest make, and good, white, cartridge paper, or that known as "cream laid," preferred to such as are coloured blue with ultramarine, for in the latter case a bleached halo is frequently perceptible around the outline of the letters, indicating the partial destruction of the colouring matter by the lateral action of the acid.

The writing produced in this manner seems indelible; it resists the action of "salts of lemon," and of oxalic, tartaric, and diluted hydrochloric acids—agents which render nearly illegible the traces of ordinary black writing ink; neither do alkaline solutions exert any appreciable action on the carbon ink. This material possesses, therefore, many advantageous qualities which would recommend its adoption in cases where the question of permanence is of paramount importance; but it must, on the other hand, be allowed that such an ink, in its present form, would but inefficiently fulfil many of the requirements necessary to bring it into common use. The peculiar method of development rendering the application of heat imperative, and that of a temperature somewhat above the boiling point of water, together with the circumstance that it will be found impossible with a thin sheet of paper to write on both sides, must certainly be counted among its more prominent disadvantages.

Though not perhaps capable of employment on the animal tissues, vellum and parchment, there is every probability of its successful application in connection with the new material produced by the action of strong acids on paper, and known under the name of vegetable parchment.

Royal Arsenal, Woolwich, Dec. 5th, 1859.

PHARMACY, TOXICOLOGY, &c.

Researches on Colocynth, by M. Walz.

M. Walz has separated from colocynth:—

1. Colocynthine C_{56} H_{82} O_{32} a glucoside.
2. Colocynthidine.
3. A resin soluble in ether.
4. A resin soluble in alcohol.
5. Colouring matter soluble in alcohol.
6. Colouring matter soluble in water.
7. Gum and mucus.
8. A liquid fatty matter.

The first is prepared in the following manner: Colocynth pounded is exhausted by alcohol. The product is evaporated to dryness in a water bath, and is then

treated with water. To this aqueous solution are added some neutral acetate and basic acetate of lead, and the liquid is filtered. The filtered liquid is yellow. The excess of lead is now removed by passing a current of sulphuretted hydrogen through the liquid, and afterwards a solution of tannin is added: a precipitate is formed which, when boiled in the mother liquor, acquires a resinous consistence. It is well washed with water, and then dissolved in alcohol: acetate of lead is added to remove the tannin, and it is then digested with animal charcoal. The golden yellow liquid obtained gives on evaporation a yellow powder, which is purified by ether. This is pure *Colocynthine*. The residue left, after treating the alcoholic extract with water, contains the *Colocynthidine*. It is soluble in ether, and so may be extracted with this menstruum. The solution is decolorised by animal charcoal, and evaporated to dryness. The residue is dissolved in absolute alcohol, from which the colocynthidine slowly crystallises out in white rhomboidal prisms.

The seeds contain less of this latter substance than the fleshy part of the fruit; but in its stead is found a very bitter oil, which communicates its bitterness to water.

Pure colocynthidine forms a bright white powder, composed of microscopic prisms. It is nearly insoluble in cold, but dissolves readily in boiling alcohol, from which part of it separates in crystals on cooling. The remainder forms a gelatinous solution, which will not crystallise for some time.

The aqueous solution of *Colocynthine* is decomposed almost instantaneously in the presence of dilute sulphuric acid, and forms a white precipitate which becomes resinous on boiling. This product, which the author calls *Colocyntheine*, has the formula $C_{44}\,H_{28}\,O_{18}$; the other product is a Carbohydrate, of the formula $C_{12}\,H_{10}\,O_{10}$. M. Walz considers it cane sugar. — *Neues Repert. der Pharm.* Bd. vii. S. 371.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY, *December 1, 1859.*

Professor B. C. Brodie, *F.R.S. in the chair.*

A paper was read by Mr. Perkins, *on the Action of Pentachloride of Phosphorus on Tartaric Acid*, by which a volatile product is obtained having the composition $C_8\,H_2\,Cl\,O_8$, and named para-maleic acid, and from this Messrs. Perkins and Duppa prepared and examined several salts. Dr. A. W. Hofmann then made a statement relative to certain discrepancies observed in the determination of the vapour densities of organic bodies. Referring to the several products obtained by Clauss through the action of ammonia on the bromide of olefiant gas, Dr. Hofmann stated that some of these were found to occupy, in the form of vapour, eight volumes instead of the four usually presented by bodies of the same class. Taking the particular instance of one of the derivatives constituted like the oxide of ammonium, he had found it impossible by any of the ordinary processes, as distillation from caustic potassa, to remove one equivalent each of oxygen and hydrogen in the form of water; but he was nevertheless compelled to consider this body as a hydrate, because sodium disengaged from it hydrogen gas. Preparing by virtue of this reaction the anhydrous substance, Dr. Hofmann found its vapour-density to be now equal to four volumes; hence he was led to the conclusion that the vapour of water, occupying itself four volumes, presented a clue to the solution of the difficulty.

A discussion followed, in the course of which Dr. Odling pointed out other examples in the chlorides of ammonium and mercury, which occupy in the state of vapour eight volumes, or the sum of that presented respectively by the ammonia and hydrochloric acid considered as separate constituents of the first; and, in the latter example, that of chlorine in addition to the space occupied by the vapour of mercury.

Dr. Hofmann then proceeded to describe an arrangement of apparatus which, with the assistance of Professor Buff, he had devised for readily demonstrating at lectures the decomposition of compound gases by the passage of the electric spark. It consisted of a Rühmkorff coil, connected with the platinum wires of Ure's eudiometer tube, arranged so that a rapid succession of sparks might be directed through a volume of gas confined in the closed limb of the instrument. Dry ammonia gas was shown by experiment to be quickly resolved into its constituents, which then occupied the double volume. The compensation for increasing pressure was regulated by the adaptation of an exit tube to the lower bend of the eudiometer, as suggested by Professor Bunsen, and by which means the level of the mercury in both limbs of the tube might be easily restored. The rapid formation of red nitrous fumes when the sparks were passed through atmospheric air; the decomposition of carbonic acid gas into a mixture of oxygen and carbonic oxide, which, when the separation had reached a certain stage, were again combined with explosion; the production from sulphurous acid gas of anhydrous sulphuric acid with liberation of sulphur; and the reduction of filamentous carbon from both light and heavy carburetted hydrogen were among the most interesting results observed in these experiments.

Professor C. L. Bloxam rose to remark that, in conjunction with Dr. Miller, he had frequently availed himself of the decomposing powers commanded by the Rühmkorff coil as a means of demonstrating to an audience the increased volume of gas resulting from the decomposition of ammonia. The arrangement usually adopted at King's College differed from that exhibited by Dr. Hofmann in the use of a straight eudiometer tube, by adjusting which at the conclusion of the experiment, until the level of the mercury both within and without the tube became the same, the production of a doubled volume was very apparent. He was much struck also with the great facility afforded by this apparatus for the exhibition of the phenomena of ozonification; as also by the very conspicuous manner in which the red nitrous fumes were developed in air, to which an increased amount of pure oxygen had been supplied.

The President then pronounced the meeting adjourned until the 15th inst., for which evening several papers were announced.

PHARMACEUTICAL SOCIETY. *Wednesday Evening, December 7th.*

T. N. R. Morson, Esq., *President, in the Chair.*

Professor Bentley exhibited a large number of beetles which had been found in a sample of cantharides. They exactly resembled cantharides in colour, but not at all in shape.

Dr. Redwood said the occurrence of such an adulteration showed the importance of a knowledge of natural history to the pharmaceutist. A man uninstructed in that science would have passed the sample without discovering the adulteration.

Professor Bentley also showed a few cantharides which had been caught in Norfolk this year. He said their appearance in England was by no means uncommon. They were found in considerable numbers in 1837, but their appearance was always confined to the three eastern counties, Norfolk, Suffolk, and Essex.

A specimen of podophyllin, said to be the active principle of the podophyllum peltatum, was also exhibited. It is a strong cathartic recently introduced into medicine.

A communication from Messrs. E. and T. Smith, of

Edinburgh in praise of their own syrup of iodine of iron was then read. Referring to a paper published in a recent number of the *Pharmaceutical Journal*, they said that the colour of the syrup was no test of its strength. Their own was colourless, and they sent a sample (*in a green bottle*) to prove the fact. If it become coloured they expose it to sunlight for a day, which bleaches it again. To ascertain whether a syrup contained its proper proportion of the iodide, they recommended that the iodine should be precipitated from a measured quantity of the syrup, by means of bichloride of mercury, in the form of biniodide of mercury; and from the weight of this the quantity of iodide of iron in the syrup could be calculated.

In the discussion which followed, a general opinion was expressed that there was no difficulty whatever in the preparation of the syrup, and that it ought always to be of a faint green colour. As to the action of light some difference of opinion prevailed, and a communication from Mr. Williams was read, in which he said, that if air were excluded, light had no effect on the syrup.

The meeting then turned to the discussion of the action of light on things in general, in the course of which, reference was made to a paper published by Sir J. Herschel, in which he stated his opinion that vegetable colours are not affected by the actinic rays, but by the colours complementary to those of the substances; but whether this effect is preservative or injurious it will be impossible to say without a reference to the paper alluded to.

Mention was made of the action of light on hydrocyanic acid, and Mr. Bottle asked which colour was best for preserving it, blue or yellow. His opinion was that yellow was the best.

The Chairman said that bottles were now sold of some inferior glass, which quickly decomposed the acid, and turned it black.

The subject of syrup of ginger was then introduced, and the propriety of varying the process of the London Pharmacopœia for its preparation was discussed.

The Chairman said he thought it would be made best with a solution of gingerine or essence of ginger, and the meeting seemed to acquiese in the opinion.

A paper by Mr. Morland on the presence of arsenic in trisnitrate of bismuth was then read.

Mr. Mohland had examined some specimens of trisnitrate of bismuth, and had only discovered mere traces of arsenic in them. He had, however, found a considerable quantity of subchloride in all. He believed the arseniate of bismuth to be almost insoluble in nitric acid, and therefore a true nitrate was not likely to contain arsenic. The oxychloride, however, might be contaminated with arsenic.

Mr. Huskisson remarked that from the way in which the trisnitrate of bismuth was made, it was impossible that it could contain more than a mere trace of arsenic. In the first place, the metal was roasted, and it was well known that arsenic was volatilised at about 397°. The metal was then digested with nitric acid, and the nitrate formed was crystallised. If any arsenic remained after the roasting, it would be found in the mother liquor of these crystals, which was poured off before the nitrate was treated with water.

The Chairman said he hoped the subcarbonate of bismuth, which he believed to be a much better preparation than the nitrate, would soon come into general use. It was best precipitated with carbonate of ammonia and a little free ammonia, which separated the copper and nickel generally found in bismuth. The best samples of bismuth, he said, contained scarcely any arsenic.

In the course of the discussion it was elicited that the oxychloride of bismuth was commonly sold for the trisnitrate, and that that might contain a good deal of arsenic.

The Chairman then made an important communication to the meeting. In consequence of receiving a letter from a country member, the Council of the Society had been in communication with the Board of Excise, relative to the question of the legality of selling *dandelion coffee* without an Excise licence. The Board had decided that to sell coffee with any admixture was a decided infringement of the Excise laws, and the members were warned accordingly. Dandelion root alone might perhaps be sold *as coffee* without a licence, but the smallest admixture of coffee constituted an infringement of the law. Permission had been given by the Board for a few admixtures of coffee with other substances to be made, and no doubt, if the Council applied, the Board would give druggists permission to make and sell a mixture of the kind, but then it would have to be expressly stated on the label what the mixture was.[1]

A question was raised whether the sale of essence of coffee without a licence was forbidden.

The meeting then adjourned till Wednesday, January 4, 1860.

NOTICES OF BOOKS, PATENTS, &c.

RECENT CHEMICAL PATENTS.

The Aniline Dyes.—Messrs. Beale and Kirkham have patented improvements in the preparation of colours for dyeing and printing. They take a salt of aniline in solution, or a saturated solution of aniline in water, and add thereto an equal quantity, by measure, of acetic acid. To this acid solution, a solution of chlorine or of a hypochlorite, as bleaching powder, is added, when the change of colour takes place and the liquid dye is produced. By varying the proportions and strengths of the materials, a variety of colours and shades may be produced. The liquor thus obtained may be used at once to dye blue; but if it be kept for a few hours it will dye purple and lilac. The dye after the exhaustion of one colour may be used for others, from blue, violet, and lilac, down to slate, brown, and straw, by the addition of more or less chlorine or hypochlorite. The proportions given are one measure of saturated aniline water, one measure of acetic acid, of five strengths, and one measure of hypochlorite of lime, sp. gr. 1010. The last must be added carefully to produce the shade of violet blue required. Instead of using the hypochlorite, chlorine may be passed through the acid solution of aniline, it being carefully watched in order that the supply of gas may be arrested when the required effect has been produced. Or, take one measure of hydrochlorate of aniline, sp. gr. 1010, one measure of acetic acid, and one measure of hypochlorite of lime, sp. gr. 1010, the last being carefully added in small quantities as before. This will produce a violet blue dye, and after a time lilacs, just as the former.

The above dyes may be used for silks without mordants.

Red Dyes.—Mr. Brooman has also obtained a patent for improvements in the preparation of red dyes. The inventors boil for fifteen or twenty minutes a mixture of aniline and anhydrous bichloride of tin At first the mixture assumes a yellow, then a reddish tint, and finally changes to a beautiful red. The mixture is liquid while hot, but when cold becomes gelatinous. The gelatinous mass is boiled with water, and filtered hot; and the colouring matter is precipitated from the filtered liquor as it cools. To completely separate this colouring matter, the patentee dissolves in the liquor either a tartrate, acetate, an alkaline or earthy chloride, an alkaline phosphate or pyrophosphate, or chloride of mercury, which precipitates the whole of the colouring matter. For dyeing, either the solution obtained by boiling the mixture in water, or the solid colour dissolved in water is used. The usual mordants, except the mineral acids, may be used with it. To obtain a solution sufficiently strong to print with, the mixture of aniline and bichloride of tin is treated while hot

[1] It ought to be known that some of the so-called Dandelion Coffee is a decided imposition, inasmuch as it is made of the root after it has been thoroughly exhausted in the preparation of the Liquor Taraxaci, and therefore is no better than [illegible] table fibre.—Ed.

with acetic acid, alcohol, or wood spirit, and the colouring matter is precipitated as before described. Another red dye is produced by mixing with aniline bichloride of mercury, perchloride of iron, or protochloride of copper, and treating this mixture as the former.

The inventor gives the name of Fuchsiacine to these colours, from their resemblance to that of the fuchsia.

Mineral Phosphates of Lime.—M. Mennons, of Paris, has patented improvements on the treatmeat of this substance. He dissolves the phosphate of lime out of Coprolites by means of hydrochloric acid, and then reprecipitates it with ammonia; and so, he says, he obtains a "thoroughly soluble and assimilable phosphate of lime for agricultural purposes."

Lubricating Cartridges.—Dr. Scoffern patents a composition for lubricating cartridges. He uses a mixture of equal weights of paraffine and naphthaline, preferring, however, a compound made by melting india-rubber in an open vessel over a fire, and thoroughly mixing with it four times its weight of paraffine, and one half its weight of naphthaline. The mixture when wanted for use is melted in an oil bath, and the temperature is kept as near 240° as possible. The advantage of the compound is said to lie in the fact that it is volatilised without change on the application of heat.

CORRESPONDENCE.

To the Editor of the Chemical News.

Sir,—On receiving your circular, it struck me that I would send you a few lines to let you know my ideas of the way in which you could best serve the interests of "the large body of pharmaceutical chemists." We have long wanted an impartial organ of free discussion, and also the earliest information obtainable respecting all matters connected with our business. But the business of a chemist and druggist must be looked at from two points of view, for it has a professional and a commercial aspect. We deal in knowledge as well as drugs. In a professional point of view we consider ourselves part and parcel of the medical profession; and we believe it impossible to separate the interests of the doctor and the druggist. We willingly accept our status as in some respects a lower one; but at the same time we believe that the intelligent dispensing of medicines is only of less importance than the intelligent prescribing of them. It is this position which we hope you will claim and advocate for us.

As tradesmen buying and selling we wish simply to be let alone. Like all other trades, we shall thrive by free competition. We ask no monopoly, not even of a name. We want no protection, not even in the sale of poisons, for practically, it would be impossible to afford it.

The great object of the Chemical News, however, should be to equalise, as far as possible, our advantages, — to bring the druggists who may happen to live at the Land's End or John o' Groat's as quickly as possible to a level, in point of information, with those who may live nearest to Bloomsbury Square. As a manufacturer of some things, I do not intend to communicate any secrets I may be possessed of, and I wish every other manufacturer to enjoy the fruits of *his own* ingenuity. If a neighbour knows or finds out a cheaper way of making any article than that I am acquainted with, by all means let him keep it to himself, and get all he can by it. But if you, as an independent journalist, become possessed of the secret, I expect you, in consideration of my three pence a week, to tell it at once; and you may do the same with any of mine when you find them out. And when a quack compound is called a new alkaloid, or a mixture of tartaric acid, carbonate of soda, and sulphate of magnesia is palmed off as citrate of magnesia, we expect you to denounce the imposition, and say that, apart from "abstract questions of morality," the thing is a cheat. Before all things, however, we expect from you a fearless exposure of everything in the shape of adulteration; for that is a sort of competition with which an honest man cannot fairly contend.

In conclusion, I would suggest a caution. You have had some predecessors who did not long survive—why, it is not hard to say. Let me advise you to avoid their faults, and then, if you honestly fulfil the programme you have issued, there can be no question of your permanent success.

I am, &c.

London, Dec. 5. M. P. S.

To the Editor of the Chemical News.

Sir,—Anticipating your appearance with much pleasure, I write at once to ask your aid and assistance in the Early Closing movement. When we have the help of such a man as Professor Wilson the time cannot be far off when we shall accomplish our object; you can help us by advocating a combination of masters to effect the desirable end. The *Pharmaceutical Journal*, of course, does not feel disposed to give us any assistance, so I appeal to you. All of us hoping one day to be masters ourselves, we consider it to be a change as desirable for them as for assistants. While we are shut up as we are, you can do us some good too by giving us good reports of the meetings, and by telling us all that is going forward in the Pharmaceutical world.

I am, &c.

An Assistant.

Chemical Notices from foreign sources, by Dr. T. L. Phipson.

I. MINERAL CHEMISTRY.

Dilatation of Gases. — M. Baudrimont[1] has lately addressed to the Academy of Sciences at Paris, a long paper on the dilatation of gases and vapours which he desires to be examined by a commission of members, and in which he thinks he has satisfactorily proved that, contrary to the opinion generally professed, the laws of Gay-Lussac and Mariotte are rigorously true for all elastic fluids, *i. e.* that all these fluids have the same coefficient of dilatation, and occupy volumes which are proportional to the pressure they support.

Aluminium. — M. Degousse[2] has succeeded in beating out aluminium into leaves as thin as those obtained with gold and silver. The operation is attended with a certain difficulty; it is frequently necessary to temper the metal; this cannot be done, however, in the ordinary manner as with silver and gold, a very slight heat only must be employed. The beating is done as usual. These thin leaves of aluminium can be substituted for silver-leaf; the colour is less brilliant than that of the latter metal, but, according to the author, aluminium-leaf is more durable, and may be employed with advantage for decorative purposes.

The metal can also be obtained in very fine powder by means of these leaves.

Aluminium in this state (beaten out into leaves) possesses a remarkable combustibility; it can be lighted with a taper like so much paper, and burns vividly with a brilliant white flame.

At the last meeting of the Academy of Sciences, at Paris, M. Dumas[3] called attention to a helmet in aluminium, manufactured by MM. De la Chaussée and Mourey. This casque is very solid and finely ornamented, gilded, &c. It only weighs 700 grammes, or about $1\frac{1}{3}$ lbs English.

Niobium.—H. Rose[4] has published many details on niobic acid. It is obtained on decomposing, by water, the yellow chloride of niobium. Niobic acid does not exist as such in the niobiferous minerals, for instance, in the Columbites

[1] *Comptes-Rendus, 1er Novembre*, 1859.
[2] *Répertoire de Chimie*, Nos. 13 and 14, 1859.

(Baierne) from Bodennais and from America, Samarskite, Euxenite, Fergusonite and Tyrite. This acid is very analogous to tantalic acid, but has a less specific gravity, and can be reduced to an inferior degree of oxidation.

Niobic acid is white after calcination, but remains yellow while hot. Sulphuric acid precipitates it completely from alcaline niobates unless fluorine compounds are present. Hydrochloric acid does not precipitate it completely, and with sulphuric acid a slight heat and repose are requisite for complete precipitation.

When a solution of an alkaline tantalate is over saturated with hydrochloric acid, and a bar of zinc introduced, the solution sometimes takes a slight blue tint; with niobates this coloration takes place much easier, and the liquid becomes first bluish grey, then blue, and soon after brown. Finally the colour disappears altogether.

Many considerations tend to prove that niobic acid, like tantalic acid, contains 2 eq. of oxygen. Hyponiobic acid is an inferior degree of oxidation, obtained from the corresponding chloride (it was formerly thought to be the oxide of another metal, *pelopium*, which, however, does not exist.) Before the blowpipe, niobic acid gives, with phosphorous salt, a colourless glass in the oxidising flame, and a brown transparent glass in the reducing flame. Hyponiobic acid gives a blue lead in the same circumstances.

Action of Anhydrous Sulphuric Acid on Sulphurets.—M. Geuther[5] has shown that when anhydrous sulphuric acid is brought in contact with sulphuret of potassium, the mixture becomes heated and evolves sulphurous acid, at the same time bisulphate of potassa is formed. With sulphuret of lead, anhydrous sulphuric acid gives rise slowly to sulphate of lead, whilst sulphurous acid is evolved and sulphur deposited. Sulphuret of antimony in the same circumstances is converted into sulphate of antimony with evolution of sulphurous acid. Anhydrous sulphuric acid has no action upon protosulphuret of iron, upon pyrites, or upon sulphuret of copper.

Protochloride of Antimony.—M. Carpentier[6] employs a weak dissolution of protochloride of antimony as a varnish for galvanised sheet-iron. Galvanised iron being protected from oxidation by a layer of zinc, cannot be blackened and rendered brilliant by plumbago, as is the case with common sheet-iron. The author proposes the use of this galvanised sheet-iron for chimneys to stoves, fire-places, &c. When washed with a diluted solution of protochloride of antimony, the metallic surface becomes covered over completely with a brilliant black varnish which is very adhesive.

II. ORGANIC CHEMISTRY.

Quinic Ether.—M. Berthé[7] has published a paper upon quinic ether. This product has excited much attention lately in France. Quinic acid discovered by Hoffman, a pharmacien of Leer, and subsequently studied by Vauquelin, Pelletier, &c. appeared destined to remain interesting only in a purely scientific light. But certain experiments made with this substance—or at least with some unknown compound of it—by some Austrian medical men, show that intermittent fever can be promptly and radically cured by the inhalation of what they took to be quinic ether, administered like chloroform, at a dose of 2 or 3 grammes. According to M. Eissen, the substance in question is obtained by distilling a mixture of sulphuric acid, quinate of lime, and alcohol. The product is a colourless liquid with an agreable odour, rather less volatile than common ether. Inhaled like chloroform, at a dose of 2 or 3 grammes on a pocket handkerchief, it easily conquers an attack of intermittent fever, and prevents any return of the attack. The object of M. Berthé's paper is to show that the product obtained as above is not quinic ether, but a complex substance which it is impossible to obtain always the same.

MM. Hesse and Clemen[8] show that quinic acid is $C_{14}H_{12}O_{12}$, as was already known, and quinic ether $C_{14}H_{11}O_{11}, + C_4H_5O$. The latter far from being a volatile liquid, is a viscid substance, completely liquid only at + 50° (centigrade) having an aromatic odour and a strongly bitter taste. It has a yellowish colour, is soluble in water (which decomposes it), and in alcohol, difficultly soluble in ether. It distils with partial decomposition at 240° to 250° (centigrade) in a current of carbonic acid. Quinic ether is prepared by the reaction of one equivalent of iodide of ethyl upon one equivalent of quinate of silver. These substances must be chemically pure and cautiously weighed. The iodide of eythl is introduced into a long necked flask of strong Bohemian glass, with the quinate of silver. The neck of the flask is closed at the lamp, and the apparatus then placed in a water bath which is heated rapidly to boiling point for one hour. After cooling, the neck of the flask is broken, and the liquid portion remaining poured out. The quinic ether and iodide of silver formed remain sticking to the sides of the vessel. This syrupy mass is treated with alcohol, and the solution filtered by evaporation to syrup, the alcohol and non-decomposed iodide of ethyl are completely volatilised, and the quinic ether remains pure.

III. CHEMICAL ANALYSIS.

Calcination of Precipitates.—M. Græger[9] recommends the addition of a known weight of peroxide of iron to precipitates which are to be calcined in presence of organic matter or carbonaceous substances which are difficult to incinerate by ordinary means. He adds 10 or 20 per cent. of recently calcined peroxide of iron to the precipitate, and the application of a slight heat is sufficient to burn away all the organic or carbonaceous matter. The peroxide of iron, which is thus reduced to protoxide, takes back its oxygen again whilst cooling.

Detection of Plumbago in Iron reduced by Hydrogen.—M. Liénart[10] has found that the *pulvis ferri*, or iron reduced by hydrogen for medicinal purposes, is sometimes sophisticated with plumbago or black lead. This fraud is easily detected by dissolving the iron first with weak sulphuric acid, and terminating the operation with aqua regia; the plumbago remaining can be collected upon a filter and examined. The author has found as much as 14 per cent. in some specimens.

Artificial and Natural Camphor.—M. Dumont[11] has shown that artificial camphor can be easily distinguished from natural camphor by its reaction with ammonia. If the two products which resemble each other so closely be dissolved in alcohol, the alcoholic solution of natural camphor will not be precipitated permanently by ammonia, whilst the other solution produces with this reagent a flocculent precipitate which cannot be dissolved in the supernatant liquid.

SCIENTIFIC NOTES AND QUERIES.

Magnetic Peroxide of Iron.—As it is proposed to give a corner for any new facts that may be noticed in the course of working or experiment, I send the following in case you may think it of sufficient interest for insertion in the Chemical News.

Some time since I was making some experiments on the black magnetic oxide of iron, one of which was to notice any peculiarity that might occur in that oxide when ignited over a spirit lamp on platinum foil; after ignition the black oxide had apparently become converted into the common red peroxide of iron, but, on applying the magnet, to my great astonishment I found that its magnetic properties remained unimpaired.

The next question to determine was, whether it was still a combination of the two oxides having undergone some molecular

11 *Journal de Pharmacologie de Bruxelles*, vol. xv. p. 442.

change or whether the protoxide had not become converted into peroxide by absorption of oxygen from the atmosphere; I therefore dissolved some of the red powder in hydrochloric acid, and to the solution added ferridcyanide of potassium, but not a trace of the proto-salt was indicated by that reagent.

The magnetic peroxide may also be conveniently prepared by fusing together for some minutes the common black oxide with 3 or 4 times its weight of nitrate of potash; prepared in this way it is more readily dissolved by hydrochloric acid than that obtained by simple ignition.

I have searched various chemical works but can find no mention of a magnetic peroxide of iron; I therefore presume that until now this peculiar compound has escaped observation.—*J. Robbins.*

Detection of Metallic Poisons in Medico-Legal Inquiries.—In Liebig and Kopp's Annual Report for 1850, English edition, p. 409, a process is given by Gaultier de Claubry for the detection of metallic poisons in organic mixtures by their electrolytic decomposition. The method is stated to be conveniently applied in judicial analyses. Has any instance been recorded of the employment of such a system? And what form will antimony and arsenic assume? will they escape as gaseous hydrogen compounds, or be deposited as reduced metal on the negative plate?—*Medicus.*

Soap Lyes.—Are the exhausted lyes of soap works treated for the glycerin they contain, or do they receive any other economic application?—*J. S.*

LABORATORY MEMORANDA.

Reinsch's Test for Arsenic.—In experimenting on different solutions of the salts of arsenic by Reinsch's test, it is very important to know that there is a considerable difference in point of time before the copper wire becomes coated with arsenic. The *Arsenites* show it almost the instant the liquid boils; whereas the *Arseniates*, or more highly oxidised salts, require a longer time and greater degree of concentration before any deposit is obtained. A knowledge of this fact may prevent an erroneous conclusion being drawn as to the presence of arsenic, although it may not be immediately detected.

In combination with chlorates, as proved by Dr. Taylor in Smethurst's case, no deposit is obtained, the arsenic remaining in solution; whilst the copper is dissolved, and imparts a blue colour to the liquid.

The *delicacy* of Reinsch's test has been greatly *underrated* by Taylor, Brande, and others, who state that arsenic fails to be detected when diluted to 120,000 times its bulk. How such a mistake should occur I cannot imagine; since, in accurate experiments lately made by me, I have detected it at a dilution of 560,000 times; and when at 280,000 times, the layer is so strong as to be fit for sublimation, having a bright steel colour: at 560,000 times, however, the deposit is more of a violet colour. These experiments were made by dissolving a grain of arsenious acid in a pint of distilled water, and diluting from time to time.

Compared with arsenic no deposit of antimony from a solution of tartar emetic took place at either of these points of dilution.—*J. Horsley, F.C.S.*

Arsenic in green Paper-hangings.—As this subject continues to excite a good deal of attention, we give a simple method by which the presence of arsenic may be immediately recognised, and if necessary, the quantity determined. Immerse a measured piece of the paper, say two square inches, in strong ammonia. If a blue colour be communicated to the ammonia, the presence of arsenic may be suspected. For a proof, remove the paper, and drop into the test glass a small crystal of nitrate of silver, which, if arsenic be present will quickly become covered with a yellow coating, which will disappear on stirring the liquid. If now it is wished to estimate the amount of arsenic, immerse the paper again in fresh ammonia until the liquid is no longer coloured blue, then evaporate all the solutions to dryness. Mix the residue with three times its weight of black flux, or carbonate of soda and sublime in a glass tube; then cut off the end of the tube, dissolve the sublimate in hydrochloric acid and precipitate with sulphuretted hydrogen; collect the precipitate on a weighed filter, wash well, dry, and weigh. Each grain of the precipitate corresponds to 0·8 of a grain of white arsenic.

MISCELLANEOUS.

Binoxide of Hydrogen.—Professor Schönbein has made the interesting discovery that during the slow oxidation of several metals (zinc, cadmium, tin, lead, bismuth, and copper) in moist air, appreciable quantities of binoxide of hydrogen are formed. The Professor, for example takes zinc filings, and makes an amalgam with mercury. This amalgam he stirs up in a tumbler with diluted sulphuric acid, by which means he reduces it to a rough powder and after well washing it he places the powder loosely in a funnel set over a bottle, and allows a thin stream of distilled water to trickle through. The presence of the binoxide in the water which has passed will be detected by the following tests which depend on the oxidising and reducing effects produced by the binoxide upon certain substances. Thin starch paste, containing some iodide of potassium, when mixed with the water, is in a very short time coloured dark blue on adding a few drops of a weak solution of any proto-salt of iron to the mixture. This test will succeed if the water contain only one-half millionth part of the binoxide. The red colour of a solution of permanganate of potash, slightly acidulated with sulphuric acid, is discharged by the dilute solution of HO_2. It will also precipitate Prussian blue from a mixture of the most dilute solutions of red cyanide of potassium and any *per* salt of iron. A dilute solution of chromic acid is a less delicate test, but it is coloured azure blue by water containing only $\frac{1}{50000}$th of the binoxide.

Water acidulated with sulphuric acid is found to give more of the binoxide than pure water, but the maximum quantity formed seems never to exceed $\frac{1}{3000}$th of the acidulated water.

Professor Schönbein supposes all slow oxidations in air to depend on what he calls the "chemical polarisation of neutral oxygen," which he is inclined to suspect is also deeply concerned in animal respiration, and many other chemical actions going on in nature.—*Abridged from a letter of Prof. Schönbein to Dr. Faraday, in the Philosophical Magazine.*

New Stopping for Decayed Teeth.—M. Feichtinger communicates the following recipe to the *Répertoire de Pharmacie*:—Take of powdered glass 1 part, oxide of zinc 3 parts, and mix them intimately. The two substances must be in impalpable powder, and the latter must be free from carbonate of zinc. Then take of a solution of chloride of zinc (density 1·5 to 1·6) 50 parts, borax 1 part. Dissolve the borax in a little hot water, and pour it into the chloride of zinc; borate of zinc is precipitated, which disappears on agitating the mixture. To make the stopping, mix the powder with enough of the solution to form a stiff paste. Only so much as may be wanted at the time should be mixed, as the compound quickly hardens. In the course of a day it becomes as hard as marble, and remains so, even after prolonged contact with water.

If the ingredients are pure, the stopping is perfectly white; but if it be required to match teeth of a yellowish colour, the necessary tint may be given by mixing a little ochre with the powder.

ANSWERS TO CORRESPONDENTS.

M. P. S.—We need hardly say that our opinions closely correspond with those of our correspondent, for whose communication we are obliged.

An Assistant.—The subject will receive early attention.

W. M.—1. The Chemical News can be obtained through any bookseller or news agent in town or country. 2. We know of no composition which satisfactorily answers the purpose. The matches must be dipped in varnish.

W. L. S.—We hope soon to satisfy our esteemed correspondent on all points.

G. M.—The subject to which you most particularly allude will receive our closet attention.

Dr. B.'s offer is declined with thanks.

R. D. Jun.—The suggestion shall be attended to.

D. Chem. Co.—We will give the suggestion careful consideration, and, if possible, comply with the request.

*** All *Editorial Communications* are to be addressed to the Editor; and *Advertisements* and *Business* communications to the Publisher, at the Office; 12 and 13 Red Lion Court, Fleet Street, London, E.C.

THE CHEMICAL NEWS.

VOL. I. No. 2. — December 17, 1859.

WHY DO SHIPS ROT?

THE question is a very important one to a nation whose Government has paid more than half a million a year for the repairs of ships of war, not to speak of the enormous sums which must have been spent in maintaining its mercantile navy in good condition. Up to the present time chemists have busied themselves more in explaining the nature of the chemical changes which take place in the wood, and in devising means for preventing the disease, than in seeking for the efficient cause of the disorder. Our readers are familiar enough with the processes of KYAN, BURNETT, and others, all of which are to a certain extent successful in preserving wood; but in spite of all, the "timber plague" still continues its ravages, and a ship laid up in ordinary, when it is wanted for sea, is sometimes discovered to be in a condition which is quite extraordinary. What this "plague" is, chemists explain to us very clearly. They say it is a process of slow combustion, in which the elements of the wood under the influence of air and moisture become converted into carbonic acid and water; and they give the process the fine-sounding name of Eremacausis. But what brings about this change? No doubt there are many causes; but a paper which we publish to-day reveals one which is perhaps the most important of all. It seems that when we build our ships we, with much effort and great noise, drive into the timber agents which are more destructive than the dreaded Black Sea worms. Hitherto it has been done in perfect innocence; but for the future we shall know that, in the opinion of an eminent chemist, and an experienced dockyard officer, one cause of the rapid destruction of the hulls of ships is IRON NAILS!

How these act in promoting this destruction our readers will learn when they peruse M. KUHLMANN's paper, which has besides a practical bearing on other important matters. M. KUHLMANN believes that the energetic action of sesquioxide of iron is one cause of the spontaneous combustion which so frequently takes place in the waste of cotton and wool, and he thinks that the place where the iron (small fragments derived from the machinery) is deposited is the probable point of departure of the fire.

But M. KUHLMANN's paper also suggests that the destructive action of the sesquioxide may be employed for a very useful purpose. He found that the hydrated oxide agitated with water coloured by various organic matters energetically decolorised it; a fact which leads us to suppose that it might be a valuable agent in the purification of waters for the supply of towns. To this part of the subject we intend to return on an early occasion.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Oxides of Iron, considered as a means of conveying the Oxygen of the Air to combustible matters, by F. KUHLMANN.

[FIRST PART.]

IN the study of the phenomena which occur in the superficial strata of the globe, no source of action must be neglected; for however weak it may be, still, when assisted by the succession of ages, it may produce the most important modifications in the constitution of the globe.

The sources of action which it is especially important to probe to the bottom, are those in which the principal agent intervenes, not by its constituent principles, but only as a sort of carrier, to transport certain bodies and place them in conditions favourable to their combination with others.

When, in our manufactories, we make use of the binoxide of nitrogen to transport the oxygen of the air to sulphurous acid, and cause the latter to pass to a more advanced state of oxidation, or when we employ acetic acid intermediately to fix the oxygen and carbonic acid of the air upon lead, we make use of one of those levers which, in nature, give rise spontaneously to the most varied phenomena.

For many years I have paid attention to these successive and slow actions, and I have indicated their importance in various memoirs. Thus I have called the attention of chemists to the part played by oxygen in the phenomena of colour in plants, and in their decolorisation by sulphurous acid, and by putrefactive fermentation. I have investigated the properties of certain bodies capable of serving as reservoirs of oxygen to convey it to oxidisable bodies, adding some facts to the important observations of M. Schönbein. My researches upon the efflorescences of walls have led me to a thorough investigation of nitrification, in which slow and successive transformations play such an important part. This investigation, which includes the action of spongy platinum upon various gaseous mixtures, led me, as early as 1846, to show that there is an intimate relation between nitrification and the fertilisation of soils. I have since explained how ammonia, the immediate product of the decomposition of animal matters, passes, under the influence of aërated water and porous bodies, to the state of nitric acid or of nitrate of ammonia, and how in the lower parts of the soil the nitric acid formed, being deoxidised by putrefactive fermentation, is brought back to the state of ammonia. I have also shown how ammonia intervenes, without decomposition, in transporting nitric acid to lime and magnesia, when the carbonates of these bases form constituent parts of arable soils, just as carbonate of ammonia intervenes to displace the silica of the alkaline silicates, giving rise to siliceous petrifactions.

Lastly, with regard to industrial applications, I have

shown how a limited quantity of carbonate of potash or soda might serve to precipitate indefinitely carbonate of lime in a pulverulent state from the chalky water which is used in steam boilers, thus preventing those incrustations which are so injurious to boilers.

A particular circumstance has lately recalled my attention to these slow and successive phenomena, in which transporting agents intervene.

Alteration of the timbers of ships. — In passing through the dockyards at Dunkirk, I had the opportunity of examining the fragments of a ship in course of being broken up, and I was much interested in observing a great alteration of the planks at all points where the wood had been traversed by iron nails or bolts. At a distance of several centimetres from these points the wood was half carbonised by a sort of eremacausis; the portions thus burnt were detached by a slight effort, the fibre of the wood having lost all its elasticity. Nothing of the kind was produced where the wood had been fixed by means of copper or wooden bolts. I have learnt from M. Frénneville that this phenomenon is general; that it is averred to be the cause of the rapid destruction of the hulls of wooden ships, and that for this reason it deserved to be thoroughly investigated.

The explanation which first of all presented itself to my mind, consisted in assuming that the iron, under the continuous action of the sea water and air becomes rapidly oxidised, and that the oxide formed, when in contact with the wood, undergoes an opposite action, and passes under this deoxidising influence from the state of sesquioxide to that of protoxide. The protoxide again takes up oxygen from the air, and transports it again to the wood, causing this continuously to undergo the alterations to which I have referred.

In this way iron would fulfil, with regard to wood, and consequently to combustible matters in general, the part played by binoxide of nitrogen in the manufacture of sulphuric acid, by acetic acid in the manufacture of white lead, &c. The sesquioxide of iron would undergo modifications analogous to those to which nitric acid is subject in arable lands, where, under the influence of the putrefaction of organic matters, it passes to the state of ammonia, to regenerate itself again at the expense of the oxygen of the air or of oxidising bodies.

It is, moreover, easy to convince oneself that it is in the properties of the iron that we must seek for the cause of the alteration of the wood; for this alteration takes place at all points where the oxide is present; it extends parallel to the fibres of the wood, as far as the iron has been capable of transportation into its thickness by the action of some solvent.

If the alteration was confined to oak timber, we might inquire whether tannin may not have had some influence in the reaction; but the same phenomena are presented by deal. It is therefore in the oxide of iron alone, whatever may be the cause of its development, that we must seek for the key of the alterations observed.

I have also ascertained that the oxide of iron fixed in the wood is not at the same degree of oxidation throughout the mass. In the state of sesquioxide it is in greater proportion in the superficial layers of the wood than in the centre, where the presence of protoxide of iron may be easily detected by ferrocyanide of potassium.

The preceding explanation supposes that sesquioxide of iron may be partially reduced merely by contact with organic matters not yet arrived at their putrefactive decomposition; the following are the results of some confirmative experiments:—

I. Hydrated sesquioxide of iron agitated in the cold with variously coloured solutions, causes their decolorisation very energetically by the formation of *lakes*. These lakes most frequently contain iron at the minimum of oxidation, the partial reduction of the sesquioxide taking place by the oxidation of the colouring matter. The colours upon which the action of sesquioxide of iron is most energetic are those of logwood, Brazilwood, cochineal, turmeric, and mahogany. The deoxidation is almost null with indigo and litmus.

These results being capable of explanation by the great affinity for oxygen possessed by certain colouring matters in the state in which they occur in plants, I had recourse, in other experiments, to organic matters presenting a closer resemblance to wood in their composition and properties.

II. Solutions of cane-sugar, glucose, and gum were boiled in presence of hydrated sesquioxide of iron. The reduction was very energetic with glucose, less so with cane-sugar, and weak with gum. With glucose the reaction is perceptible even in the cold.

III. Lastly, I tried the action of oil of bitter almonds upon hydrated sesquioxide of iron dried at 212° F. The reaction took place in a sealed glass tube, which was kept at a temperature of 212° F. for ten hours. In this experiment a large quantity of protobenzoate of iron was produced. A portion of the oxide remaining undisturbed was in the state of protoxide.

We may add that the phenomena of destruction of organic matter in contact with oxide of iron, without the intervention of the deoxidising gases of putrefactive fermentation, are going on daily before our eyes. There is no one who does not know from experience that after one or two washings, spots of iron-mould in linen or cotton stuffs are replaced by holes; printing with iron presents the same defects, and too often stuffs dyed black acquire a brown tint; when, as they lose their strength, they are suspected of having been *burnt in dyeing*.

I shall add the following facts, observed during a long experience of bleaching by one of my pupils, M. Dietz:—

I. When the inner walls of the sheet iron washing troughs are laid bare by the removal of the calcareous incrustrations which usually cover them, and the iron comes into direct contact with the stuffs, the latter become covered with rust in the upper parts to which the air has free access, and in all the portions so spotted their alteration becomes inevitable.

II. When the common stuffs manufactured with the cotton waste contain scales of iron, produced from the cards or other parts of the machinery, this iron becomes rusted during the bleaching operations, and in four or five days the stuff is in holes, wherever the rust was deposited.[1]

It appears evident to me that this energetic action of sesquioxide of iron may be one of the causes of the spontaneous inflammations so frequent in the waste of cotton and wool. If the oxidation of the oils with which these materials are often impregnated be a circumstance in favour of these inflammations, the place where the

[1] M. E. Schwartz, who has paid attention to the causes of the alterations which I have indicated, asserts that, in dyeing, the protoxides of iron and manganese which are deposited upon the tissues and oxidized with the view of obtaining sesquioxide of iron and binoxide of manganese, often cause "the oxidation of the tissue itself upon which they are applied," and he establishes this proposition,—"*that a substance in becoming oxidised also causes the oxidation of the body in the presence of which it is, even when the latter is not oxidisable in an isolated state.*"—(Persoz, *Traité de l'Impression des Tissus*, I. p. 311.) I think that the considerations upon which I have entered will not bear any doubt in the minds of chemists as to the actual cause of the alteration of tissues. For the oxidation *par entraînement* assumed by M. Schwartz, I substitute a succession of reactions which has no limit except the destruction of the combustible material.

oxide of iron has been deposited is probably the point of departure of the fire.

The results of my experiments, and all these facts of daily observation, appear to be conclusive in making chemists to admit that sesquioxide of iron may serve to convey the oxygen of the air to organic matters, and thus hasten their destruction. This oxide acts to a certain extent as a reservoir of oxygen, filling itself at the expense of the air in proportion, as it empties itself for the profit of the combustion of combustible bodies.

As regards the alteration of the timbers of ships, now that the causes of this alteration are indicated, it will be sufficient no doubt for its avoidance that the iron nails and bolts should be tinned or coated with zinc, or replaced by nails and bolts of copper.

In the second part of this memoir, I shall take up the agronomic and geological questions attaching to it.—(*Comptes-Rendus*, 1859, *p.* 257.)

On Isomeric Alkaloids, by C. Greville Williams.

While investigating the organic alkaloids produced by destructive distillation, I was struck by the almost entire coincidence of the formulæ of the bodies found from the most opposite sources. Thus coal, bituminous shale, Dippel's oil (bone oil), and cinchonine, all appeared to yield alkaloids belonging to the same series. But although the composition of the same alkaloids from each source was identical, and even their boiling points agreed as well as could be expected, yet there were differences in the smell, power of forming crystalline salts, &c. which presented themselves during the course of these long investigations, and at times almost induced a belief that I was dealing with isomers instead of identical bodies. The greatest differences were found with the bases produced by destructive distillation of cinchonine. Here the odour of the alkaloids was so different to that of the same bodies extracted from other sources that I long oscillated between two opinions. However, the resemblances were too numerous to justify me in announcing the pyridine series, as obtained from cinchonine, to be a new class of alkaloids. In fact, the absence of absolutely distinct reactions rendered such a course impossible. I have, however, at length discovered a reaction with the chinoline series as obtained from cinchonine, which is so totally different from anything which can be obtained with the chinoline series from coal tar, that I am fully persuaded of their being essentially different.

Chinoline, or lepidine from cinchonine, was boiled with iodide of amyle for a few minutes, after which water was added, and the boiling continued for a short time. The product was a brown oily looking fluid suspended in the water. A little ammonia was now poured in, and the boiling continued for a short time longer, when the whole of the oil became converted into a magnificent blue colour of the utmost intensity. It dissolves readily in alcohol, and the diluted fluid dyes silk of a fast and most brilliant blue, having a slight shade of purple.

So strong is the attraction of silk for the dye that the bath becomes colourless, every trace of colour being taken up. It has but small tendency to unite with cotton, for if the latter, after being dyed blue, be boiled with silk, the cotton becomes colourless and the silk absorbs all the colour.

The coal tar bases of the same composition present nothing similar. They may, it is true, be made to yield superb colouring matters, but by totally different modes of procedure.

I am at present endeavouring to ascertain whether the pyridine series from cinchonine possess any features sufficiently distinct from the same series as extracted from coal, to justify the conclusion of their being a distinct class.

TECHNICAL CHEMISTRY.

The Analysis of Platinum Ores, by MM. Deville and H. Debray.

The ores of platinum contain the following substances:—

1. Sand. The whole of the sand is never removed by washing the ore; and the sand contains quartz, zirconium, chromate of iron, and, in the Russian ores, titanate of iron.

2. Osmide of iridium.

3. Platinum, iridium, rhodium, and palladium, combined no doubt in the form of an alloy.

4. Copper and iron which exist in the ores in a metallic state, for the iron found in the sand is not soluble in acids.

5. Gold, and, oftener than is supposed, a little silver. The latter metal is generally found with the palladium, and it is very rarely that palladium is obtained quite free from silver when it is prepared by the old processes.

1. **Sand.**—To estimate the sand we take a small assay crucible, or an ordinary crucible with smooth sides, and melt in it a little borax, so as to glaze the inside. We now introduce from 7 to 10 grammes of pure granulated silver, and 2 grammes of the ore, fairly taken and weighed very accurately. Over the platinum we put 10 grammes of fused borax, and one or two small pieces of wood charcoal. The silver is now melted, and care must be taken to keep it for some time a little hotter than the melting point, so that the borax may be very liquid, and may dissolve the vitreous matters which accompany the platinum and constitute the sand. The crucible is now allowed to cool, and when it is cold, the button, which will contain the silver, osmium, platinum, and all the other metals is detached, and if necessary digested for a time with weak fluoric acid to remove the least portions of borax. It is now heated to a faint redness, and then weighed. The weight of the button subtracted from the sum of the weights of the ore and silver employed, will give the amount of sand contained in the ore. For example:—

	Milligr.
Californian ore	2000
Silver	·7221
	9221
After fusion, the button weighed . . .	9162
Consequently the ore contained, sand . . .	59

It is very important to know this number, for it represents the only matter absolutely destitute of value which the ore contains; and this simple operation may be considered the most important performed in estimating the value of an ore. It is, besides, performed so quickly that it is as well to do at the same two or three specimens, taken from different parts of a lot of platinum powder.

2. **Osmide of Iridium.**—Another 2 grammes of the ore weighed very accurately are treated with aqua regia at 70° (Cent.) until the platinum is entirely dissolved. The aqua regia must be renewed occasionally for 12 or 15 hours, or until it is no longer coloured. It is best to perform this operation in a large beaker, and to place a cover over it to prevent loss. The solutions must be decanted with the greatest care from the metallic spangles of the osmide of iridium and the sand which remain at

the bottom of the beaker. If necessary it may be filtered, but as little as possible of the osmide must be allowed to go on the paper. The insoluble residue must be washed by decantation, then dried and weighed, after having added what remained on the filter. By subtracting the weight of this residue from the weight of the sand obtained in the former operation, we obtain the weight of the osmide of iridium. For instance, in the Californian ore we had :—

	Milligr.
Osmide of iridium and sand	81
Sand	59
Osmide of iridium	22

The button obtained in determining the sand, might be employed in this operation. In that case it is necessary to dissolve out the silver with nitric acid, and then proceed with the residue, as we have just directed.

3. **Platinum and Iridium.**—The solution in aqua regia obtained in the last operation is evaporated to dryness at a low temperature, and the residue is redissolved in a small quantity of water (if it should not entirely dissolve in the water some more aqua regia must be added, and the evaporation repeated), to which is added about twice as much pure alcohol; lastly, we add a great excess of sal ammoniac in crystals. The whole is now slightly warmed to complete the solution of the sal ammoniac, it is then stirred, and afterwards set aside for 24 hours. The orange-yellow, or even reddish-brown precipitate which is formed contains the platinum and the iridium, but some remains in the solution. The precipitate must be thrown on a filter and washed with alcohol. Afterwards the filter is dried in a platinum crucible, placed, for greater safety, within a larger one, and afterwards heated by degrees to low redness. The crucibles are now uncovered, and the filter is burnt at the lowest possible temperature. Once or twice after the incineration of the filter a piece of paper saturated with turpentine should be introduced into the crucible, by which means the oxide of iridium will be reduced, and the expulsion of the last traces of osmium will be effected. The crucible is now heated to whiteness until it no longer loses weight, or the reduction is finished in a current of hydrogen.

The liquid separated from the platinum-yellow by filtration, is evaporated until the chloride of ammonium crystallises in great quantity. It is allowed to cool, is then decanted, and on a filter is collected a small quantity of a deep violet coloured salt, which is the ammoniochloride of iridium mixed with a little of the platinum salt. This is first washed with a solution of sal ammoniac, and then with alcohol. The salt is then ignited, and if necessary reduced by hydrogen like the platinum salt. The mixture of platinum and iridium obtained by the two reductions is then weighed. The two metals are now digested at about 40° or 50° (Cent.) in aqua regia, diluted with about 4 or 5 times its weight of water—the aqua regia being renewed until it is no longer coloured. The residue is pure iridium. To obtain the weight of the platinum the weight of the iridium is subtracted from that of the mixture of the two. This method of separating the two metals is very accurate if the aqua regia used be weak, and the contact with it is prolonged.

4. **Palladium, Iron and Copper.**—The liquor charged with sal ammoniac and alcohol, from which the platinum and iridium have been separated, is evaporated to get rid of the alcohol, and then treated with an excess of nitric acid, which transforms the chloride of ammonium into nitrogen and hydrochloric acid. It is now evaporated almost to dryness. The residue is removed to a covered porcelain crucible which is weighed with great care. When the matter is dry it is moistened with concentrated hydrosulphuret of ammonia, and afterwards dusted over with 2 or 3 grammes of pure sulphur. When dry, this crucible is placed within a larger one of clay, and surrounded with pieces of wood charcoal. The two covered, are now set in a cold furnace which is filled up with charcoal, and the fire is lighted at the top to avoid the projection of any matter from the crucible, if it were too quickly heated. After reaching a bright red heat, the crucibles are allowed to cool. The porcelain crucible now contains palladium in a metallic state, with the sulphides of iron and copper, and also the gold and rhodium. This mixture is moistened with concentrated nitric acid which, after prolonged digestion at 70°, dissolves the palladium, iron, and copper, forming at the same time a little sulphuric acid. The solution of the nitrates is poured off the residue which is washed by decantation, and the solution and washings are evaporated to dryness, and then calcined at a strong red heat. In this way the palladium is reduced, and the iron and copper pass to the state of oxides, which are easily separated from the palladium by means of strong hydrochloric acid. The palladium remains in the crucible in which it is again strongly ignited and then weighed.

The chlorides of iron and copper are now evaporated to dryness at a temperature but little above 100° (Cent.), and are then treated with ammonia. The sesquichloride of iron having lost nearly all its acid, has become insoluble; but the chloride of copper is readily dissolved, and may be filtered from the iron which is washed, ignited, and weighed. The copper solution is now evaporated almost to dryness, and then mixed with excess of nitric acid, and heated to drive off the chloride of ammonium. Afterwards the nitrate of copper is ignited and weighed. The weight of the copper is always so small that the hygrometric water the oxide of copper may absorb may be neglected.

5. **Gold and Platinum?**—The residue insoluble in nitric acid is weighed and treated with very dilute aqua regia, which takes up the gold, and sometimes, but very rarely, traces of platinum. To ascertain if platinum be present, evaporate to dryness, and redissolve by alcohol and chloride of ammonium. If any platinum-yellow remain, it must be ignited and weighed. The difference in the weight of the porcelain crucible before and after the treatment by aqua regia, gives the weight of the gold, from which, if any be found, the weight of the platinum must be deducted.

6. **Rhodium.**—The residue left in the crucible is rhodium, which must be reduced in a current of hydrogen.

We append the results of some analyses of platinum ores, by MM. Deville and Debray.

ANALYSES OF PLATINUM ORES FROM VARIOUS SOURCES.

	Columbia.	California.	Oregon.	Spain.	Australia.	Russia.
Platinum	80·00	79·85	51·45	45·70	59·80	77·50
Iridium	1·55	4·20	0·40	0·95	2·20	1·45
Rhodium	2·50	0·65	0·65	2·65	1·50	2·80
Palladium	1·00	1·95	0·15	0·85	1·50	0·85
Gold	1·50	0·55	0·85	3·15	2·40	(1)
Copper	0·65	0·75	2·15	1·05	1·10	2·15
Iron	7·20	4·45	4·30	6·80	4·30	9·60
Osmide of iridium	1·40	4·95	37·30	2·85	25·00	2·35
Sand	4·35	2·60	3·00	35·95	1·20	1·00
Osmium and loss	. .	0·05	. .	0·25	0·80	2·30
	100·15	100·00	100·25	100·00	100·00	100·00

(1) Gold, if any, counted in the loss.

In conclusion, the authors caution experimenters who may follow in their steps to beware of the ill effects of osmium, which particularly attacks the eyes, and also to avoid breathing the vapour from the aqua regia. — *Annales de Chimie et de Physique.*

On the Production of the Purple and Rose-red Murexide Colours in Cotton Printing, by Dr. Von Kurrer.

Murexide may be used in stuff printing, either in a powdered or pasty state. It need neither be chemically pure nor crystallised, because in such conditions it is too high in price.

A. Printing with the Colour.— In 72 pounds of boiling water, 24 pounds of crystallised nitrate of lead are dissolved; and when the solution has cooled to 144° F. 5 pounds of dry, powdered, or 15 pounds of pasty murexide are dissolved in the fluid, and afterwards 36 pounds of finely powdered gum; after which the whole is passed through a handkerchief or a fine sieve, and left to cool, in which state it may be employed either for hand or roller printing.

After printing, the stuffs are hung up in a damp place until the impressed part feels soft, when the purpurate of lead is fixed upon the fibres by means of gaseous ammonia. This is best effected by hanging the stuffs in a hermetically closed chamber, such as is used for the sulphuring of woollen and silken tissues, by means of sulphurous acid. In place of the sulphurous acid produced by the combustion of sulphur, in this case gaseous ammonia is evolved from caustic lime and muriate of ammonia.

B. Passage of the Stuffs through the Sublimate Bath.—The pieces of stuff treated with gaseous ammonia are now passed through a bath containing in 1500 pounds of water, 2 pounds 11 ounces of corrosive sublimate (bichloride of mercury), previously dissolved in water.

In this bath each 3 pieces, of ¾ wide and 60 Brabant ells long, united together, are passed backwards and forwards; then for each following 3 pieces, 3 ounces of sublimate, dissolved in water, are added. It depends on the pattern whether a greater or less number of pieces can be passed through the heated bath.

Light patterns enable 30 pieces of stuff of the above dimensions to be treated in the same bath; whilst with heavy designs a fresh bath must be prepared after 20 pieces have been treated.

As soon as each three pieces have passed through the sublimate bath, they are hung in flowing water until the pieces are collected, when they are passed together through the acetate of soda bath in an ordinary dye trough.

C. Acetate of Soda Bath.—This consists of 3000 pounds of water, into which 1 pound of acetate of soda and 1 pound of muriate of ammonia have been stirred.

In this bath 10 pieces of stuff attached to one another are passed to and fro over the *harpel* for twenty minutes, then washed clean in running water, freed from water in the wringing apparatus, and dried cold.

In the same bath, furnished with 1 pound of acetate of soda, but with no muriate of ammonia, 10 pieces of stuff are again treated.

In this way prints of the most brilliant purple-red colour are produced. For pale gradations, in order to produce patterns in these different red shades, namely, dark-red, middling and pale rose-red, the normal colour for the two latter gradations receives a proportional addition of pure gum-water.

Cotton stuffs printed with murexide colours may be soaped without injury at 144° Fahr.; the colour also perfectly resists chlorine in the machine without any alteration; on the other hand, it is destroyed by hot aqueous vapours, and it is therefore impossible to combine murexide with the ordinary steam colours, such as green, blue, yellow, &c.

In cotton stuffs dyed with a single murexide red colour, the ground colour may be destroyed in particular spots, partly by oxidising and partly by deoxidising agents, and thus illuminated prints of the most beautiful and various patterns may be obtained. Thus by printing with acid zinc salts, orange figures are produced.

Dark grey figures are obtained by printing with protosalts of tin. Murexide printed upon medium pale-blue grounds produced with indigo, furnishes a remarkably fine violet. Stuffs dyed yellow with yellow vegetable pigments, receive figures of a Turkey-red colour when printed on with murexide.

Silken and woollen fabrics dyed of a uniform red with murexide, may be bitten with yellow by means of picric acid, when the latter is mixed with an acid capable of decolorising murexide. In the same way other active substances may be used for printing various figures of different colours.

D. Preparation of Murexide Plate-printing Red. For the plate printing of cotton fabrics, murexide will also be advantageously employed, when to 1 quart of the above-described purple colour are added 2 ounces of bichloride of mercury, and 2 ounces of acetate of soda, each dissolved in half a pint of water. The stuffs printed with this colour are hung up for three to four days, and then watered in the same way as in ordinary plate-printing. Murexide, however, can only be printed with wooden blocks, because brass decomposes the bichloride of mercury, and changes the colour; this is also the case in roller printing. — *Polytechn. Centralblatt*, 1859, p. 337.

Modern Applications of Chemistry.

Since there appears to exist in the community such very widely different opinions as to the extent to which chemical science is capable of being advantageously applied, it may perhaps be well in a periodical which is likely to be read by so large a section of the general public, to draw attention to the causes of this difference of opinion, and to point out that chemistry is neither on the one hand the magic wand which divines all secrets, nor on the other is it a mere system of theoretical ideas producing few immediate or practical results. It cannot fail to excite astonishment when we reflect on the rapid advance which natural philosophy has made in recent times, and how differently its study is appreciated now from what it was but a few years ago. Instead of being scarcely recognised as one of the branches of learning to be cultivated in our colleges and schools; an acquaintance with its principles is now considered as an essential part of a liberal education. Of all branches of natural philosophy, none has of late years been a more general favourite than chemistry, and none has exercised so important an influence upon the progress of the arts and manufactures; and it is doubtless to this capability of application to the wants and requirements of every-day life that chemistry is indebted for the position it holds at the present day. Notwithstanding, however, the general knowledge which

now exists of this science, there is still a great deal of misapprehension as to what it ought to be expected to perform. There are many who imagine that a thorough theoretical knowledge of the science is sufficient to entitle the possessor to be regarded as an authority on all questions, manufacturing or otherwise, in which the principles of the science are involved. They assume that because they are acquainted with all the chemical changes which take place in any manufacturing process, that they are capable of undertaking any such operations, and of conducting them with greater skill and efficiency than men long practised in their particular callings, who have not the advantage of the same amount of theoretical information. On the other hand there are many engaged in various branches of manufacture, who, although unacquainted with the theory of the processes they adopt, have nevertheless by long experience, and by close and attentive observation of facts, made themselves so thoroughly masters of their business as to render it difficult for any less practised hand, however high his scientific attainments, to show in what manner his processes could be curtailed or improved. Such men are too apt to conclude that the ability to draw a correct and logical theory is but of minor importance, and are slow in perceiving the vast amount of time and labour which such theoretical knowledge, combined with their own experience, would save them in deciding on the value of the numberless proposed improvements which are every day forced upon their notice, and upon a correct judgment on which their commercial position may depend.

There can be no question that a thorough acquaintance with theoretical principles is the only basis upon which a sound knowledge of the science can be attained, but it should not be forgotten that however profound such theoretical knowledge may be, long practical experience is necessary before a thorough acquaintance with any of the varied manufacturing operations, to the successful prosecution of which chemistry is now so essential, can be acquired. If we recall to mind how the application of chemistry to any branch of industry has gradually developed itself, we cannot fail to perceive how the exaggerated estimate formed by some of its value has induced others to ignore altogether the advantages it is capable of conferring.

We are indebted to the publication of Liebig's letters on agriculture and the chemistry of food for the attention of the people of this country being first attracted towards chemical science. A new light appeared to have dawned upon the world which seemed to promise to make the most obscure processes clear as noon-day. Surprised and delighted at the simplicity of what had hitherto been so little understood, over-sanguine minds jumped at conclusions which proved to be fallacious, and decried as useless all practices that could not be logically explained. Nothing could apparently be more perfect and unquestionable than Liebig's theory of agriculture. Assuming that plants can obtain sufficient nitrogen from the air, the conclusion seemed obvious, that so long as the soil is supplied with the inorganic constituents of the plants grown upon it its fertility must remain unimpaired. Further experience, however, proves that the system pursued by practical agriculturists is correct, and that plants require more nitrogen than they obtain from the air and than they retain in their composition. Whether this nitrogen acts (as has been suggested) as a carrier of silica, or what other purpose it serves, is still unknown, but the fact is not the less established that nitrogen must be supplied in large quanties if a continuation of good crops is to be maintained. The first analyses of guano were very minute, very useful in a scientific point of view, but almost worthless for practical purposes, inasmuch as they afforded no data from which its value could be ascertained. It was not until the beneficial properties of artificial manures were found to depend principally upon the proportion of nitrogen and phosphates they contained that analysis of them could be considered to bear any relation to their money value. We now find them sold by analysis as regularly as soda ash by its degree of strength, without the correctness of such a mode of valuation being called in question.

Again, the idea that chemistry could be of service to the ironmaster or iron manufacturer has been looked upon as chimerical. It is true that the first results of chemical investigation in this direction only went to prove to how great a degree of perfection the processes of smelting and working iron ores had been brought, how well adjusted were the proportions of fuel and fluxes, and how judiciously the impurities of one ore were counteracted by admixture with others of a different character. Had the theory of these processes been as well understood as they now are, these results, arrived at by long practice, would have been more easily and speedily attained, in proof of which we have only to observe the rapid advances which have been made in the manufacture of iron within the last few years. We sometimes hear it argued that the chemical constitution of cast iron is no test of its quality. To some extent this may be admitted, inasmuch as an iron free from any objectionable matter may nevertheless, from mechanical causes, not possess the requisite strength and toughness; but it is no less true that an iron containing impurities beyond certain well ascertained limits can never be strong or tough, no matter to what process it may be subjected, so long as these impurities remain.

The effect of phosporous, silicon, and sulphur, upon the physical properties of iron are now well understood, and it is just as impossible for cast iron containing 5 per cent. of silicon to be otherwise than weak and brittle as it is for lead containing 1 per cent. of arsenic to be soft. It is true that to the practised eye of the ironmaker the quality of cast iron is rendered evident by the character of its fracture, and that chemical analysis is not always necessary in order to ascertain its value; but analysis is not the less of service in showing the cause of inferiority, if such exists, and in pointing out the best method of correcting it. When we call to mind the mistaken views which scientific men have too often upheld from not basing their theories upon experiments conducted on a sufficient scale, we can scarcely be surprised at finding the experienced manufacturer very cautious in adopting opinions which do not appear to be borne out by practice; preferring to continue a process, the reason of which he may be unable to explain, until it is indisputably proved that the desired result can be attained without it. If chemists would bear in mind that laboratory experiments are not always attended with the same results when carried out on a larger scale, they would less frequently have to retreat from positions the too eager defence of which has not been without detriment to their credit and prestige. With every year chemistry widens its sphere of action, affording full scope for those who labour in the fields of purely scientific research as well as for those whose minds have been cast in a more practical mould, and we cannot doubt that the more generally an aquaintance with the principles of the science is cultivated, the more highly will the services it renders to society be increased and appreciated.

PHILO-TECHNOLOGY.

PHARMACY, TOXICOLOGY, &c.

CHINOVINE.

The matter extracted from the cinchona barks, and known variously as chinovic acid, red cinchonic, cinchonic bitter, has been made the subject of a long investigation by H. Hlasiwetz and Dr. von Gilm. They have decided that it is a glucoside having the composition $C_{60}H_{46}O_{16}$. In an alcoholic solution, under the influence of chlorine, this breaks up into a sugar which the authors consider identical with the mannitane of Berthelot, and an acid which they call chinovic acid, a change explained thus:—

$$\underbrace{C_{60}\,H_{48}\,O_{16}}_{\text{Chinovine.}} + 2\,HO = \underbrace{C_{48}\,H_{28}\,O_8}_{\text{Chinovic acid.}} + \underbrace{C_{12}\,H_{12}\,O_{10}}_{\text{Mannitane.}}$$

The acid falls as a crystalline powder. These crystals are washed with weak alcohol, and then dissolved in strong boiling alcohol, from which they crystallise. The crystals appear to be regular six-sided prisms. They are insoluble in water, only slightly so in ether, but more soluble in boiling alcohol. They dissolve freely in ammonia and the fixed alkalis. All the solutions are bitter. The mineral acids displace the chinovic acid from its combinations, the acid separating as a gelatinous mass. It is feebly monobasic, and decomposes the alkaline carbonates. The salts of potash and soda are uncrystallisable. Those of baryta, strontia, and lime, prepared by double decomposition, fall as gelatinous precipitates soluble in an excess of water. The chinovate of silver falls as a voluminous precipitate which is very sensible to light. Nitric and sulphuric acids have no action on chinovic acid.—*Chem. Central Blatt*, No. 52.

THE EXTRACTION OF POTATO STARCH.

In the manufacture of this article a considerable quantity of the product is lost owing to the strong affinity the starch has for the fibre of the potato. From M. Anthon's experiments on the subject, it appears that the manufacturer only extracts two thirds, and that the remaining third is left in the pulp. M. Anthon suggests that this third may be utilized by converting it into sugar, by means either of malt or dilute sulphuric acid. By employing 10 per cent. of the acid to the dry fibre, the saccharification is completed in about two hours and a half; but if only 3 or 4 per cent. of acid is used, the boiling must be continued for at least five hours. Ten per cent. of malt effected the conversion in six hours. The result as to the quality and quantity of sugar produced is the same whether it is obtained by malt or sulphuric acid. — *Chemisch Central Blatt*, 1859, 33—513.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY, *November* 3, 1859.

(THE FIRST MEETING DURING THE PRESENT SESSION.[1])

Professor B. C. Brodie, *F.R.S., in the Chair.*

A Paper was read by Dr. Edward Smith, Assistant-Physician to the Brompton Hospital for Consumption, detailing the results of experiments in continuation of those already communicated by him to the Royal Society (January 20th, and February 10th, 1859), and by which he has been led to several interesting facts explanatory of the phenomena of respiration. The inquiry commenced with the determination of the average amount of carbonic acid and aqueous vapour expired from the lungs after an interval of several hours' fasting; and in the second place comprehended the influence exerted by various kinds of food in disturbing this normal amount, under conditions both of rest and muscular activity. The apparatus employed by Dr. Smith to measure the air inspired consisted of a small dry gas-meter or spirometer, through which a full supply was conducted to the individual, whose mouth and nostrils were covered with a small mask; the products of respiration were passed first into a desiccator containing sulphuric acid to absorb water, and thence into a gutta percha box, divided into numerous compartments, and charged with caustic potash, by which the carbonic acid was retained. The author concludes that his experiments have established the existence of a class of foods to which the term "excito-respiratory" may be applied, and which comprehend nearly all nitrogenous articles of diet, also sugar, coffee, and especially tea, the latter causing a greater evolution of carbon than it supplied. The most remarkable among the "non-excitants" were starch and fatty substances. The administration of alcohol produced results differing according to the nature of the sample: rum and spirits of wine always increased the evolution of carbonic acid, while brandy tended on the contrary to diminish the activity of the respiratory process.

A short discussion followed the reading of this Paper, in which Drs. Gilbert, Harley, and Marcet, and Mr. Alfred Smee took part.

Professor C. L. Bloxam then read a short account of *The Hydrates of Baryta and Strontia*, in which, after referring to the uncertainty regarding the composition of the crystallised hydrates, he stated the results of his experiments to have led him to the formulæ $BaO + 9\,HO$, and $SrO + 9HO$ respectively. The baryta compound was obtained by boiling together the nitrate of baryta and caustic soda, when it separated on cooling, and was easily purified by two or three crystallisations. The crystals so produced effloresced in air of the ordinary condition of dryness, and lost seven equivalents of water in vacuo over sulphuric acid or on exposure to the temperature of the water oven. The hydrate of strontia imitated the deportment of the baryta compound, excepting in the result of heating to redness, when, contrary to usual statements, it loses all its water, becoming converted, as would lime, into the anhydrous condition.

In connection with the subject of Mr. Bloxam's paper, the President exhibited a specimen of precipitated anhydrous peroxide of barium, as obtained by adding baryta water to the solution of the crude peroxide in cold hydrochloric acid, which he considered well worthy of more extended investigation.

Thursday Evening, November 17.

Dr. W. A. Miller, *in the Chair.*

A description of an hermetically sealed barometer was communicated by Mr. Adie of Liverpool. The instrument, constructed of glass, is described as being very sensitive to slight differences of atmospheric pressure; it is compensated for temperature, but on account of its indications being disdisturbed by the effects of partial heating, the method of suspension by a cord when in use was recommended. It is to be regretted that no model or drawing of the instrument accompanied the written description.

A note relative to the more perfect purification of the lead compounds obtained in the preparation of the fluorescent substances, paviin and æsculin, from horse-chestnut bark, was communicated by Professor G. G. Stokes.

The theoretical views advanced by Dr. Kolbe in reference to the relation existing between lactic and propionic acids,

[1] In order that the readers of the Chemical News may be placed in possession of a complete record of the meetings of this Society during the present session, we now give an abstract of the two meetings which took place previous to the publication of our first number.—Ed.

became then the subject of discussion, in which Dr. A. W. Hofmann and Dr. Odling took part; after which the meeting was adjourned.

NOTICES OF BOOKS, PATENTS, &c.

A Manual of Qualitative Chemical Analysis, by A. Beauchamp Northcote, F.C.S., Demonstrator to the Professor of Chemistry at Oxford; late Senior Assistant in the Royal College of Chemistry, London; and Arthur H. Church, F.C.S., of Lincoln College, Oxford; late Assistant to Professor Brodie. London: Van Voorst.

Chemists still talk of organic and inorganic chemistry as if the two branches were two trees of different families. So little do some appreciate the unity of the science, that, forgetting, or not even knowing how truly (like a hypothetical republic) it is one and indivisible, they speak of "organic chemists," and we once heard a distinguished cultivator of the science spoken of as "*only* an organic chemist." It is on this principle of division that by "qualitative chemical analysis" is always understood the qualitative analysis of inorganic bodies. Treatises on the subject, it is true, usually contain tables for the detection of a few of the more important organic acids, but the qualitative analysis of organic bodies generally has not as yet been reduced to rules. The reason of this is that chemists of the Bracconot school exist no longer. The proximate analysis of mixtures of animal and vegetable substances is still a problem bristling with difficulties. If difficulties exist then there is honour to be gained in overcoming them. Let us hope that chemists will soon begin to search for a little honour in this direction.

The time has been when qualitative analysis was a charming study. But the days when a skilful analyst could scarcely take up the investigation of a few minerals without being rewarded by the discovery of a new substance or new combination of substances has passed away, never perhaps to return. The pleasures derived from chemistry are principally due to the gratification of curiosity. Those alone who really love it, know the feeling with which a working chemist applies himself to the solution of a problem. As soon as the matter can be reduced to rule nine tenths of the charm has fled. This then is the reason why the compounds of carbon are now more investigated than the products of the so-called inorganic world. Let any one read Klaproth's Analytical Essays, throwing himself back as it were into the time, let him read the description of his attempts to dissolve the precious stones, his delight at the advent of the "flint grinding dish," his proof of a specific difference between baryta and strontia, founded on the difference in their atomic weight[1], let him, we say, read this, and he will see how delightful a pursuit inorganic analysis has been. It is almost impossible now to place oneself in a similar position towards any save organic bodies. Here problems present themselves at every step for solution, here there are seldom rules of such universal applicability as to prevent the necessity for the use of judgment and ingenuity.

The treatise before us is one of the books the very value of which depends on the perfect manner in which it brings analysis (at least so far as can be done without reference to quantities) within the scope of any one possessing an average amount of patience and intelligence. Written by men who are not only perfectly and practically familiar with the subject, but who have for years been engaged both in teaching and making investigations, it possesses an amount of authority which we cannot accord to the productions of those who, for aught that the chemical world know to the contrary, never made an investigation or even an analysis.

The unitary system having been adopted in some of the principal laboratories, it became desirable in order to avoid confusing students to give them text-books having the symbols and equations in the new notation. The present work has been written not only with this view, but also to enable advanced students to make qualitative analyses of the rare substances so often omitted in elementary treatises.

One feature in the work before us is especially deserving of notice, namely, the perfect order, method, and sequence of the reactions. For example, in describing the properties of substances, the salts are not put down at random, but in the order of basity, thus mono-, bi-, and then tribasic salts. In like manner the reagents employed are always in the same order, the characteristic reactions being printed in bolder type, so as at once to arrest the attention.

The directions to students as to the proper method of pursuing their analyses, and the precautions necessary to ensure success, are all excellent. We understand that Professor Brodie has made this manual his laboratory text-book. We are sure that he will find the correctness of his judgment confirmed by the rapidity and ease with which his students will advance.

On the Comparative Value of certain Salts for rendering Fabrics non-inflammable: being the substance of a Paper read before the British Association at Aberdeen, by F. Versman, F.C.S. and Alphons Oppenheim, Ph. D., A.C.S.

Women have a right to complain that while men have expended an immense amount of ingenuity in protecting themselves from one element—witness the enormous number of patents for rendering fabrics mostly employed for male garments *waterproof*—they have done very little to protect women from the more dangerous and domestic element—fire. We are happy to see that something has been done to wipe away the reproach; and it ought to be known that it has been done at the command of her Majesty, at whose request the Master of the Mint employed the authors of the above paper to make experiments, the use of the royal laundry being granted for the purpose. Here, and at other places, the authors tried every salt they could think of, and some salts which few persons would ever have dreamt of employing. Of the substances used, however, two only seemed to fulfil all the purposes required. These are sulphate of ammonia and tungstate of soda; but as both of these salts are soluble, the difficulty of *fixing* an anti-inflammable substance in a fabric has yet to be overcome. For laundry purposes only the tungstate of soda can be recommended, inasmuch as the sulphate of ammonia sometimes produces brown spots like iron-moulds, when the fabric is ironed. The tungstate, however, offers one difficulty, viz. the formation of a bitungstate of little solubility, which crystallises from the solution. To obtain a constant solution, a small percentage of phosphate of soda must be added. "The best way of preparing a solution of minimum strength is as follows:—A concentrated solution of tungstate of soda is diluted with water to 28° Twaddle, and then mixed with 3 per cent. of phosphate of soda. This solution was found to keep and answer well, and has been introduced into her Majesty's laundry." We think her Majesty would be pleased if the authors were to inform her subjects exactly how this solution is used in her laundry; and we shall be happy to be the medium of the communication. Appended to the paper are tables, showing the smallest percentage of salts required in solution for rendering muslin non-inflammable, from which we learn that of crystallised tungstate of soda, 20 per cent., and of anhydrous, 16 per cent. are required; and of crystallised sulphate of ammonia 7 per cent. of anhydrous 6·2 per cent. are wanted.

An Improved process of Manufacturing Sulphate of Lead, Carbonate of Lead, Nitrate of Potash, and Sulphate of Soda. W. E. Newton: a communication.

The inventor first granulates his lead finely by melting and pouring through a perforated vessel into water. He then

[1] Klaproth showed that they evolved different quantities of carbonic acid when treated with acids.

places it in a suitable vessel which he charges with nitric acid. After standing for some time the acid is drawn off into a second vessel with a quantity of similarly prepared lead, and this is repeated a third time. The nitrate of lead, now supposed to be neutral, is then treated with sulphuric acid, which precipitates the insoluble sulphate of lead, and the nitric acid is drawn off to be used in another operation.

The above process may be modified in the following manner:—A saturated solution of nitrate of soda is decomposed by sulphuric acid. The nitric acid of the nitrate of soda is thus set free, and sulphate of soda is formed. The whole is then heated in vessels of stone ware, or enamelled iron, and metallic lead is introduced, which is rapidly dissolved by the nitric acid. The nitrate of lead thus formed is immediately decomposed by the sulphate of soda, an insoluble sulphate of lead, and nitrate of soda being the result. The sulphuric acid is replenished from time to time, until all the lead is dissolved, when the liquid nitrate of soda is drawn off to be used with fresh quantities of lead and sulphuric acid as before.

The sulphate of lead is next decomposed by carbonate of potash and nitrate of soda, whereby are obtained carbonate of lead, nitrate of potash, and sulphate of soda. For this purpose 25 pounds of sulphate of lead are added to a saturated solution of 10 pounds of pearlash in water, which are changed by double decomposition into carbonate of lead and sulphate of potash. The solution of the latter is separated from the insoluble carbonate of lead, and is then decomposed by the addition of nitrate of soda, 12½ pounds being added for the above quantities of sulphate of lead and pearlash. The result is the production of saltpetre and Glauber salt, which are separated by crystallisation.

This process may also be varied as follows: "The nitrate of soda may be first decomposed by the pearlash by boiling them together, the result being nitrate of potash and carbonate of soda, the former to be separated by crystallisation. The carbonate of soda is then employed to decompose the sulphate of lead, and the result as before is carbonate of lead, nitrate of potash, and sulphate of soda; or the nitrate of soda, the sulphate of lead, and the pearlash, may be mixed together, whereupon a triple decomposition will take place. The carbonic acid of the pearlash uniting with the lead, the nitric acid of the soda with the potash, and the sulphuric acid of the sulphate of lead combining with the soda, and forming, as before, carbonate of lead, nitrate of potash, and sulphate of soda."

The above processes it must be confessed are very ingenious.

An improved means of giving increased strength to Paper.
THOMAS TAYLOR.

THE invention consists in soaking paper (either sized, unsized, or partially sized) in a concentrated solution of neutral chloride of zinc, either warmed, or at the ordinary temperature of the air. The solution must have the specific gravity of 2100, or thereabouts, when it will have the consistence of syrup. The paper to be treated must be immersed in, or floated on, the solution until it is fully saturated; it is then removed and washed with water. If it is desirable to retain a portion of the zinc in the paper, it is, after being partially washed, immersed in a weak solution of carbonated alkali, and then thoroughly washed in water. After this treatment it will be found that the paper is more or less changed, has contracted in volume, become more dense, less porous and much stronger. When it is desired to produce a more complete change, the solution must be heated, and the temperature may be varied from 80° or 90° F. to 212°, according to the effect desired. The change is completed when the paper becomes swollen, and apparently dry, as well as opaque and flaccid. If sheets of paper saturated with the solution be pressed together and ironed, they will become permanently united. In some cases the patentee dissolves cotton fibre, starch, dextrine or gum in the solution of chloride of zinc, or he adds the chlorides of tin, calcium, or magnesium; but the paper is always submitted to a thorough washing with water.

Paper thus treated, assumes more or less the toughness, semi-transparency, and general appearance of parchment.

Our readers will remember that Mr. Gaine produced the same effect on paper by immersing it for a few seconds in oil of vitriol diluted with half its volume of water. The change in both cases is no doubt essentially molecular. We should like to know whether the whole of the chloride of zinc is removed in the washing.

CORRESPONDENCE.

Modern Theories of Chemical Notation.

To the Editor of the CHEMICAL NEWS.

SIR,—There was a period in the infant days of chemical science, when facts were few and theories but crude, and when those who acknowledged the name of chemist were masters of the science in all its bearings. Times, however, have changed, and chemistry is now divided into numerous distinct branches, each offering a wider field for investigation than did the parent science itself in its earlier stages.

We thus have chemists organic and inorganic; chemists who devote their attention to analysis, scientific and commercial; chemists who are engaged in unravelling the mysteries of photography and kindred sciences. Again, we have the manufacturing branches, in which we find chemists labouring to improve the arts of dyeing, brewing, and the preparation of artificial manures; chemists who are busy in the production of lead- and zinc-whites, mineral and other pigments; in converting the ammoniacal liquors of gas-water into sulphate of ammonia for the manufacture of alum and for sale to the agriculturist. Indeed, refuse of all kinds is sought to be turned to account by men who depend on chemistry for converting things of little or no value into marketable articles.

Each and all of these are guided in their labours by the facts and laws left ready to their hands by the scientific workers who have gone before. It is therefore necessary, when utilitarian views are thus uppermost in the minds of the many, and to a great extent justly so, that an occasional glance should be turned to the first principles of the science, in order to see that these keep pace with the facts constantly brought to light by more practical men.

With regard to organic chemistry, we are sufficiently active in this direction; scarcely a journal appears, but we see numerous facts given to the world, which are immediately ticketed and set apart by those who devote themselves to their classification, arranging them, of course, according to their particular views of the subject.

The frequent recurrence of difficulties in such a classification, has given rise to numerous modifications in the old views of chemical science, and we are not at present agreed amongst ourselves, as to which of these should be preferred, for although we may allow one class of bodies to look particularly well, when dressed according to a certain fashion, yet we find them as particularly ill-looking and out of place when an arrangement is adopted which shows to advantage another class of substances. Yet notwithstanding this unsatisfactory state of theory as regards organic chemistry, we cannot too highly appreciate the untiring labour of those who devote time, energy, and attention, to the study of the groupings of the thousand and one acids, bases, alcohols, and aldehydes at present known through that branch of the science. The other division of chemistry, which takes cognisance of the inorganic world, has likewise its votaries, although less numerous than those of the newer and apparently more fascinating kingdom governed by the elements C H O and N. In the old study of the relation of acids

to metallic oxides, and the reaction of salts upon each other, new facts are yet brought to light which are of sufficient interest to engage the attention of the few who still labour amongst the laws governing the mineral kingdom, and we have, therefore, some theorists who are just as busy keeping watch and ward over these facts on their appearance, as is the case in the other department.

And now, sir, what is the relation existing between these two branches of the same science, do they acknowledge the same fundamental principles? Are the elements which we assume as forming the basis of both, governed by the same laws under the different circumstances in which we find them placed by the different experimenters? To this we must unhesitatingly reply in the affirmative, and yet we see them under such apparently irreconcileable phases as almost to induce a doubt as to the reality of the fact.

The explanation of this must be sought for in the different manner in which organic and inorganic chemists regard the reactions of the elements and chemical changes in general. The existence of this discrepancy in the opinions formed by two persons viewing general phenomena in different lights, becomes more evident when we engage their attention on one in which we can place the theories side by side. Take for example water:—On one side we are told that water is the protoxide of hydrogen, and that its formula is HO; on the other hand we hear that it is more truly represented by $\frac{H}{H}O$, or two particles of hydrogen to one of oxygen; another time we find that the simplest portion recognised is a combination of atoms tabulated thus, $H_2^2O_2$

This is one of the examples of viewing the same substance with the eyes of the inorganic and organic chemist. No doubt each has good reason for giving the preference to one or other of these formulæ, but that such diversity of opinion should exist seems to indicate a strange want of understanding respecting the basis of chemical combination.

Neither can we compromise matters and say that all these forms are correct, that it is only as a matter of convenience that we represent water under these different phases, just as we are in the habit of writing at one time AmCl, at another NH_4^2Cl, or KCy and KC_2N. These cases are quite different, for $Am = NH_4$, and $Cy = C_2N$; but H is not equal to H_2, neither can 2 $\left(\frac{H}{H}O\right)$ be strictly formulated by $H_2^2O_2$: equal this latter might be, but by the peculiarity of its arrangement it is meant to represent something fundamentally different, and which could not be recognised by the grouping 2 $\left(\frac{H}{H}O\right)$.

We have then this question: "What is the proper way of expressing in chemical language that simplest of all compounds, water?" In the answer to this lies the clue to the solution of the difference we now observe in the notation of the two systems of Chemistry, and I think you will be ready to admit the incalculable benefit which would accrue from a full ventilation of the question at issue between the partisans of of the different theories.

***

To the Editor of the Chemical News.

Sir,—A report has become almost universally diffused tending to the disgrace of the Chemical Society. As I can scarcely believe it to be true, I think it right to give the Society the opportunity of directly, or through one of its members, contradicting it.

It is said, that the distinguished chemist, M. Sainte Claire Deville, having been proposed as an honorary member, was blackballed from a personal feeling against the proposer, himself one of the most brilliantly successful chemists in Europe.

Now, Sir, as the Chemical Society have, ever since they existed, shown their unwillingness to hurt any candidate's feelings by blackballing him, even when such candidate was utterly unknown to science (as may be seen by looking through a list of the Fellows), I cannot think they would commence with such a man as M. Sainte Claire Deville.

Trusting you will give insertion to the above in the hopes of some light being thrown upon the affair,

I am, &c.

Aluminium.

Chemical Notices from foreign sources, by Dr. T. L. Phipson.

I. MINERAL CHEMISTRY.

Specific Gravity of Vapours at very High Temperatures.—The determination of the density or specific gravity of vapours produced by bodies whose point of ebullition surpasses the temperature at which glass becomes soft, appeared an almost impossible problem in the actual state of chemistry. The highest temperatures in the experiments of Dumas and of Mitscherlich for the determination of densities, never ranged above 500° (Centigrade). MM. H. Sainte Claire Deville and L. Troost[1] have, however, succeeded in taking the densities of several vapours at very high temperatures, by conquering the three difficulties which arrested former experimentalists, viz. the nature of the vessel employed, the constancy of the temperature employed, and thirdly, the estimation of this temperature.

The vessel is of porcelain; it has a long neck which can be closed when required by the flame of an oxy-hydrogen blowpipe. The constant temperature at which the density is determined is produced by the vapour of a body whose point of ebullition is much higher than that of the substance experimented on.

The vapours destined to furnish this constant temperature are produced in a distillation apparatus of iron, which the authors have already described (*Comptes-Rendus*, xlv. p. 821). The substances employed to effect this are mercury for a temperature of 350°, sulphur for a temperature of 440°, cadmium for 860°, and zinc for 1040° (Centigrade).

As to the temperature, the authors have avoided the difficulties which attend its exact determination by operating comparatively, and in precisely the same conditions, with the substance whose density it is required to know, and another substance the density of whose vapour is known with certainty. MM. Deville and Troost have preferred to compare their operations with the vapour of iodine, as the great weight of this vapour renders the errors of weighing much smaller. Their experiments give them, directly, the relation existing between the density of the vapour experimented on and that of the vapour of iodine.

The following results have been obtained:—At 860° (Centrigrade) the density of sulphur vapour is 2·2, and remains about the same at a temperature of 1040°. Thus, the anomaly which was supposed to exist in the law of gaseous equivalents concerning sulphur disappears: when the density of sulphur vapour is taken at a temperature sufficiently remote from that of the point of ebullition of sulphur, the results are such that we may admit, without hesitation, that the equivalent 16 of sulphur represents 1 volume of vapour, as the equivalent 8 of oxygen represents 1 volume also.

The density of selenium vapour presents the same peculiarities as the preceding: at 860° it is = 8·2; at 1040° it is = 6·37. Theory indicates 5·44—a difference which it will require further experiment to elucidate.

The vapour of phosphorus at 1040° is 4·5. Theory gives 4·4 in admitting that 1 equivalent of phosphorus represents 1 volume of vapour. At 1040° the density of cadmium vapour is 3·94. By theory we obtain 3·87 in admitting that the equivalent of cadmium represents 2 volumes of vapour.

Bromide of aluminium vapour gave 18·62, theory = 18·5, 2 volumes; iodide of aluminium vapour gave 27·0, theory = 27·8, 2 volumes. These numbers were calculated by means of the apparent dilatation of air or iodine vapour in porcelain

[1] *Comptes-Rendus*, xlix. p. 239.

vessels, which do not sensibly augment in volume at the highest temperatures.

Iridium.—At the last meeting of the Academy of Sciences at Paris, M. Pelouze[1] presented some medals struck in alloys of iridium, consisting of: 1. platinum 80, iridium 20; 2. platinum 90, iridium 10; 3. platinum 95, iridium 5. These alloys were obtained at the demand of M. Jacobi, of St. Petersburg, by MM. Sainte Claire Deville and Debray.

The alloys in question can be rolled cold, and are easily tempered; they are harder than gold money at $\frac{916}{1000}$ths. This degree of hardness, and their capacity for resisting *aqua regia*, augments with the proportion of iridium. They are also capable of receiving a fine polish. The metals were obtained from a platinum ore extracted from the mines of Prince Demidoff, at Nijni-Tagilsk; this ore containing platinum 92·55, iridium 7, rhodium 0·45. The ore itself has been employed for medals, which are remarkable for their tenacity.

M. Jacobi[2] presented to the Academy a bar of iridium weighing 267 grammes, which was melted by MM. Deville and Debray in a crucible of lime, the combustible being a mixture of hydrogen and atmospheric air. In this experiment these authors substituted hydrogen gas for carburetted hydrogen (or common gas), which they employed in their experiments on platinum.

M. Regnault has determined the specific heat of this bar of iridium, and has found that the law of Dulong, which determines the relation existing between the specific heat and atomic weights of bodies is perfectly applicable to iridium. Former experiments tended to prove the contrary because they wer emade with impure samples of the metal in question.

On the Octahedric Oligist of Vesuvius.—The presence of crystals of oligist in the crater of Vesuvius, where they appear to result from sublimation, has often puzzled chemists. Some believe these crystals to have been formed by the sublimation of chloride of iron, which is afterwards decomposed into oxide, retaining the same form. Professor Rammelsberg[3] appears to have nearly solved the problem. The octahedrons of Vesuvius gave him on analysis:—

	I.	II.
Peroxide of iron	82·91	83·30
Magnesia	13·60	13·41
Oxide of copper	0·99	0·59
Insoluble portion	2·51	2·00
	100·01	99·30

The density of the sample I. was 4·568, and that of sample II. 4·638. Deducting the oxide of copper and the insoluble portion, these figures lead to the formula 2 MgO, 3 Fe_2O_3 or 3 MgO, 4 Fe_2O_3.

By heating together common salt and sulphate of iron, crystals of oligist are formed, and if the crucible be hermetically closed, magnetic oxide of iron in the form of a black powder is produced.

Magnetic oxide can also be obtained, according to M. Rammelsberg, by heating to redness some protochloride of iron in a glass tube, in presence of a current air and watery vapour. A black mass sublimes, which has a crystalline and at the same time cavernous aspect, and which is nearly pure magnetic oxide. Chloride of iron and chloride of magnesium being heated in the same conditions, Professor Rammelsberg obtained another black mass, which, after washing with water and acetic acid, gave the composition:—

	I.	II.
Peroxide of iron	67·46	69.00
Protoxide of iron	14·42	12·43
Magnesia	17.94	16·69
	99·83	98·12

This analysis conducts us to the formula 3 (MgO, FeO), 2 Fe_2O_3. The author explains by this experiment the production of the Vesuvian octahedrons, and proposes for them the mineralogical name *magnoferrite*.

[3] *Pogg. Annalen*, civ. p. 497; and *Comptes-Rendus*, xlix. p. 218.

II. ORGANIC CHEMISTRY.

New Colouring Matter.—M. Horace Kœchlin[1] announces that he has succeeded in obtaining a new, and, to all appearance, very important red colouring matter, by adding an acid (in preference hydrochloric acid) to a mixture of aniline and common pyroligneous acid. Wood-tar produces the same result as pyroligneous acid, which proves that acetic acid has nothing to do with the production of the colour. The substance obtained by M. Kœchlin somewhat resembles that lately introduced into commerce by M. Frank, and which has been called *fuchsine*; it is as yet, however, little known.

Gutta-Percha.—Professor Bleekrode[2] has lately presented to the *Société d'Encouragement pour l'Industrie Nationale* an interesting Notice on gutta-percha. [In the *Annales des Sciences Naturelles, Botanique*, vol. vii. p. 220, M. Bleekrode has shown that the commercial prices of this useful substance vary exceedingly. In the markets of Amsterdam, in 1857, they ranged from 7*d.* to 2*s.* 9*d.* the kilogramme (about 2lbs. English) on some 234,975 kilogrammes imported from the Dutch possessions of the East Indies. The consumption of gutta-purcha is increasing daily. "In the Dutch possessions," according to the author, "the exportation increases daily, whilst the imprudent manner of collecting the substance from the *Isonandra-percha* (at Singapore, an English possession) is gradually diminishing the production: in cutting down an Isonandra (*Njeto*) of 1 metre 50 in circumference, 160 grammes only are collected; whereas a tree that is only 90 centimetres in circumference furnishes at each bleeding, in the rainy season, 79 grammes, and in the dry season 138 grammes; being a total in one year of 217 grammes."

Another plant of the same variety, *Sapota Mulleri*, also furnishes a species of gutta-percha, which has been already tested in industry; it is collected easily without sacrificing the tree. The trunk is partially or totally encircled by a kind of clay basin, which collects the juice exuding from the incisions. At Surinam, this milky juice becomes solid in six hours. By testing it with alcohol, the author obtained from a specimen of this, which was rather spoiled during the voyage, 14·28 per cent of pure white gutta-percha.

Metals in the Blood.—M. Béchamp[3], of Montpellier, has communicated to the Academy of Sciences at Paris the results of some new analyses of blood, made with a view of ascertaining whether certain metals, such as manganese, copper, lead, &c. entered into its normal composition. He arrives at a negative conclusion, and asserts that these metals are only found accidentally in the blood, and do not constitute essential elements of its composition. It has been shown long ago, that iron is an essential element of this fluid; and, some years back, Dr. Hannon, professor of botany at Brussels, showed that the blood contains manganese, a discovery that has been since confirmed by other chemists. What proof have we then that M. Béchamp's analyses be the rule and not the exception?

III. CHEMICAL ANALYSIS.

Oxide of Copper for Organic Analysis.—Pure oxide of copper employed for organic analysis, is generally obtained by the calcination, in copper vessels, of nitrate of copper. In this manner, not only all the nitric acid is lost, but the abundance of nitrous vapours renders the operation disagreeable and unwholesome. MM. Vogel and Reischauer[4] propose a new preparation, as follows:—A solution of ammoniacal nitrate of copper heated to boiling point deposits black oxide of copper, whilst ammonia is evolved and neutral nitrate of ammonia remains in solution. An excess of copper is therefore dissolved in nitric acid, the solution, filtered or decanted

[1] *Répertoire de Chimie*, No. 12, 1859.
[2] *Bulletin de la Société d'Encouragement.*
[3] *Comptes-Rendus*, Dec. 5, 1859.
[4] D'Ingler's *Polytechnisches Journal*, cliii. p. 197.

off, is divided into two equal portions. To one of these, liquid ammonia is added until the precipitate which forms, is redissolved, and a clear blue liquid, $2AzH_3, CuO, AzO_5$, is obtained .The other portion is then poured in. A blue basic salt is precipitated, but enough ammonia remains in solution to transform this basic salt into oxide of copper when the liquid is heated to boiling. The ebullition takes place in the sand-bath, and black oxide of copper is deposited rapidly. The neutral nitrate of ammonia which remains in solution contains however a little copper, which gives it a blue tint. The metal is separated by sulphuretted hydrogen, and by evaporation the clear liquid furnishes pure nitrate of ammonia, a salt frequently employed for refrigerant mixtures.

Detection of Picric Acid in Beer.— Picric, or carbazotic acid, has often been employed to give a bitter taste to beer, and so economise the quantity of hop. M. Doré[1] informs us that Lassaigne's test will detect in beer the presence of $\frac{1}{15000}$ths of picric acid. It consists in adding subacetate of lead and animal charcoal to the beer in question, and shaking the mixture thoroughly. When the liquid has remained quiet for a little while, if the beer is pure it will be seen quite devoid of colour; but if even a very slight quantity of picric acid has been added to it, the liquid, after the above operation, will not lose its yellow colour.

SCIENTIFIC NOTES AND QUERIES.

Sir,—As one who has had a somewhat extensive acquaintance with chemists and druggists for many years, I firmly believe that a publication bringing before them new preparations, and giving trade hints and helps, would be warmly supported by them; and I hope a good portion of the Chemical News will be devoted to this purpose. Will you give insertion to the following in your *Notes and Queries*?—After making the underwritten prescription, and allowing it to stand a few hours, crystals are freely formed—(the patient tells me that she has had it made up to remain perfectly clear). What are those crystals? and how are they formed?

℞	Sodæ Sulphat.	ʒj.
	Magnes. „	℥ss.
	Ferri „	9j.
	Liq. Calcii Chlorid.	ʒij.
	Aquæ Font. ad	ʒviij.—Ft. Mist.

An answer will oblige.—*J. R.*

[The crystals are most likely sulphate of lime. Their formation may depend a little on the order in which the ingredients are mixed. The sulphates should first be dissolved in the whole quantity of *cold* water, and then the chloride of calcium may be added.—Ed.]

Determination of Phosphates in Soils, &c. — Sir,—Can you or any of your readers give me a good and easy process for the estimation of phosphates in soils and the ashes of plants? All the processes given in books are complicated or not satisfactory, and it may be some of your readers may know of better which they will be glad to communicate.—*H. D.*

Syrup of Iodide of Iron.—Sir,—A few weeks ago I made some syrup of iodide of iron in the usual way, which looked very nice, but was perhaps a little greener than usual. When, however, I come to dilute the syrup, in making a mixture there always falls a precipitate of small bright yellow crystals. What can these be? I am afraid to use it in dispensing until I know. *B. G.*

LABORATORY MEMORANDA.

To Gild Aluminium.—Digest a weak solution of chloride of gold with a little excess of lime for twenty-four hours. Well wash the precipitate of aurate of lime and lime, and then treat it at a gentle heat with a solution of hyposulphite of soda. The filtered solution can be used for gilding without the help of a battery. The aluminium must be previously freed from any oxide by successive washings with potash and pure nitric acid.

[1] *La Science pour Tous*, Dec. 1, 1859.

Detection and estimation of small quantities of Lead in the presence of other metals.—The separation of lead from its solutions and from other metals by means of chromate of potass, does not appear to have attracted the attention of analytical chemists to the extent which it merits, judging from the published special methods of analysis which include the determination or detection of that metal.

There are frequent instances in which the chromate of potassa offers considerable advantage as a precipitant of lead over hydrosulphuric or sulphuric acids, the two reagents in general use, more particularly for the detection of minute quantities.

The efficiency of this reagent is moreover much increased by the circumstance that chromate of lead is all but insoluble in acetic acid. It is indeed one of the most insoluble of the lead salts, and has, therefore, claim to superiority over the more soluble sulphate; whilst the scarcity of insoluble chromates renders chromate of potassa valuable for effecting the separation of lead from other metals in cases where the reagents referred to are inapplicable. The precipitation of lead in the presence of copper, for example, is more readily effected by the addition of bichromate of potassa to an acetic solution; a trace of lead which would otherwise escape detection is rendered evident after a time by the deposition of the characteristic yellow precipitate.

Bichromate of potassa in the presence of free acetic acid is also applicable as a means of separating small quantities of lead from zinc (*i.e.* in the analysis of the spelters of commerce). The precipitation of lead by hydrosulphuric acid from the hydrochloric solution, is at times anything but satisfactory, the solubility of the sulphide of lead in the excess of hydrochloric acid which must be employed to prevent the precipitation of the zinc is sufficient to lead frequently to the belief that lead is absent when it really exists in the spelter to a very appreciable amount. (It may be observed that this liability to error, in the use of hydrosulphuric acid, is not nearly so great when nitric acid is employed).

If much bismuth be present in the substance under examination, some chromate of bismuth will be precipitated, together with the lead. In such instances the separation of the two metals must be effected by a special method.

The chromate of lead when freshly precipitated from a cold solution is sometimes difficult to separate perfectly from the liquid by filtration; this is not the case, however, if the precipitate is allowed to stand for some time, or if it is produced in a hot solution.

The most accurate way of determining the weight of minute quantities of lead precipitated as chromate, is to convert the metal finally into sulphate. For this purpose the chromate is dissolved in a little hot dilute hydrochloric acid; a small crystal of tartaric acid is added, and the solution, rendered alkaline by ammonia, is treated with hydrosulphuric acid, or mixed with a few drops of sulphide of ammonium. The sulphide of lead thus obtained is washed and converted into sulphate by the usual method.

Chemical Department, Woolwich.

ANSWERS TO CORRESPONDENTS.

A Novice.—1. The processes "are equally efficacious for the extraction of the virtue from the Sarsaparilla." That made by the second method would keep best — but it is not a *decoction*. 2. It would not spoil for a week or two, if kept in a bottle *quite full*, and well corked. Left open to the air, most decoctions and infusions will spoil within a week in winter, and two days in summer, and sometimes in much less time. 3. An ounce of rectified spirit to the pint would probably answer, but it would be absurd to add it to any other than a concentrated infusion or decoction.

Prescription.—If not directed, "or to saturation," the dispenser would have no right to put more than the quantity of alkali written. Citric acid is now often prescribed in excess.

X. Y. Z.—We cannot undertake to recommend wholesale houses. Our correspondent must find his market for himself.

A Junior.—It is got rid of perfectly by boiling, but this boiling must be continued for some time.

M. P. S.—(London.) To answer your question might subject us to trouble which we do not care to incur, but the fact is as stated in the note. It would be difficult, if not impossible, to detect the fraud, which perhaps increases the criminality.

Ph.—The oil will always separate, and the mixture must be shaken before it is used.

M. B.—Chloric Ether, so called, is not an ether, but a solution of chloroform in spirit. It is kept of various strengths, there being as yet no recognised formula. Mr. Haselden has shown that a mixture of one part chloroform and nine parts spirit is the most convenient to employ.

W. J. S.—Try the yellow prussiate and pernitrate of iron.

*** All *Editorial Communications* are to be addressed to the Editor; and *Advertisements* and *Business* communications to the Publisher, at the Office; 12 and 13 Red Lion Court, Fleet Street, London. E. C.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Remarks on Parkes's Method for the Estimation of Copper by means of Cyanide of Potassium, together with a brief Review of the Modes usually adopted for the Determination of Copper, by FREDERICK FIELD.

[FIRST PART.]

IN one of the numbers of the *Mining Journal*, in the year 1851, Mr. Parkes published a method for the volumetric determination of copper, by means of a standard solution of cyanide of potassium. The process is so well known, and has been so generally adopted, that a detailed account of the *modus operandi* would be unnecessary. The substance containing copper is dissolved, ammonia added in excess, and solution of the cyanide dropped carefully into the dark blue liquid until the colour disappears.

Towards the latter stage of the process, however, the decolorisation is not very distinct, the solution assuming a delicate violet tint, which fades very gradually, leaving at length the liquid destitute of colour. Great caution and considerable practice are required to determine the necessary amount of cyanide. There can be no doubt that it is requisite to allow the liquid to stand for some time (a quarter of an hour or twenty minutes) towards the close of the operation; and if the colour is not expelled after that period a few drops more cyanide must be added, the flask well agitated, and the solution once more left at rest. Indeed, it is always safer to leave a very slight tint, as it disappears after the lapse of twelve or fourteen hours. Since the publication of Mr. Parkes's method, I have made considerably more than fifteen thousand estimations of copper by the cyanide process, comparing it with many other well-known modes of determination, in order to test its accuracy, and to observe the influence which solutions of other metallic oxides possess when in conjunction with that of oxide of copper.

In the case of copper ores, containing copper either combined with sulphur, as disulphide or protosulphide; with sulphuric acid, as *brochantite* or *cyanose;* with oxygen, as suboxide or protoxide; with carbonic acid, as the *blue and green basic carbonates;* with chlorine, as *atacamite;* with phosphoric acid, as *tagilite*, &c.; as arsenide in *Domeykite* or *algodonite*, and with arsenic or arsenious acid, provided no iron be present; in alloys of copper and tin or copper and antimony; double sulphides of copper and iron, either as yellow or blue pyrites, the copper can be estimated with exactness by cyanide of potassium.

Now, in all copper ores containing iron, it is far better to add the cyanide to the ammoniacal solution, *without filtering off the suspended peroxide of iron.* Every chemist knows with what tenacity this oxide holds an ammoniacal solution of copper. Even after several hours washing with warm liquid ammonia, the copper cannot be separated; and although the liquid may pass through colourless, on rewashing, after a day or two, the filtrate will have a decided blue tint. The test first proposed, I believe, by Mr. Warington (and which, decidedly, is the most delicate one for the presence of copper which we possess), viz. ferro-cyanide of potassium, never fails to show the presence of copper in the peroxide of iron, even when hydro-sulphuric acid or ammonia are unable to detect it. If a small quantity of copper with a large excess of iron be dissolved in nitric acid, a considerable quantity of ammonia added, and the two metals separated by filtration, after washing for several days, on taking a small portion of the oxide of iron, dissolving in hydrochloric acid, adding ammonia and filtering, a drop of the ferrocyanide added to the filtrate in a white capsule, is sure to give a pink stain on the porcelain, when the excess of ammonia has been expelled by a gentle heat. There is no need whatever for filtering off the oxide of iron, and the estimation of copper can be effected in a very satisfactory manner without undergoing filtration.

In copper slags, for example, which generally contain from 0·2 to 0·8 per cent. of copper, and from 40 to 50 per cent. of iron, it is impossible to determine the former metal, with any degree of accuracy, by the addition of ammonia and subsequent filtration. Cyanide of potassium added to the liquid in which the oxide of iron remains suspended, is capable of estimating the amount of copper with considerable exactness. A rim of liquid, more or less blue, gradually appears above the precipitating oxide, a few drops of the standard decolorising solution are added, the whole well agitated, and allowed to rest, until the clear liquid reappears. If still strongly coloured, more cyanide is required, and this operation is continued until the liquid has a pale violet, or rather, rose-coloured tint. It is then left for some time, and if the shade do not seem to fade, a small quantity more is added. The result of numerous estimations prove, that small quantities of copper can be determined very successfully by this means; and when several slags or other metallurgic products have to be examined, the method is very convenient, as, while the oxide of iron is subsiding in one flask, another assay can be undergoing decolorisation from the burette, and so on.

In order to test the accuracy of the process, two or three experiments may be cited from among a great many which have been made. A mineral containing simply sulphur, iron, and copper, with a little quartz, gave in five determinations: —

	31·4	per cent. Cu.
	31·5	" "
	31·3	" "
	31·4	" "
	31·4	" "
or a mean percentage of	31·4.	

Four estimations were made by precipitating the copper from the solution of its oxide in hydrochloric acid, by means of metallic iron: —

	31·38	per cent. Cu.
	31·42	" "
	31·47	" "
	31·44	" "
Mean	31·427.	

Two determinations were effected by the precipitation of the copper as sulphide by means of hydrosulphuric

acid, and subsequently weighing as protoxide in the usual manner:—

Cu calculated from CuO 31·384
" " " " 31·402
Mean 31·393.

These experiments prove that copper may be estimated with considerable exactness by means of cyanide of potassium.

In each determination, 50·000 grains of mineral were taken, and the solution of cyanide formed by dissolving 1300 grains of the salt in four pints of water. A solution of this strength may be kept many days without undergoing decomposition, although it is always better to make a preliminary experiment, from time to time, in order to see that the standard is the same.

In alloys of *tin and copper*, the copper may be determined without difficulty.

In alloys of *antimony and copper*, the copper can be estimated with ease.

In the case of *arsenic and copper*, the latter metal can be determined very readily. A specimen of *Domeykite*, given to me by its discoverer, M. Domeyko, yielded by this process 71·6 Cu, M. Domeyko finding 71·64, and theoretically, 71·91 (Cu_3As). And it may here be remarked that the cyanide of potassium does not in any way interfere with the estimation of the arsenic. In fact, it rather facilitates the determination, as the washing of the arseniate of ammonia and magnesia ($2Mg.O.NH_4O.AsO_5+HO$) is more easily effected from the ammoniacal cyanide of copper than from the solution of cupric oxide in the volatile alkali. When arsenic acid and copper exist together in a liquid, the addition of ammonia in excess still holds them both in solution, and when sulphate of magnesia is added, the ammonio-magnesian arseniate is precipitated. It very seldom happens that this precipitate can be entirely freed from copper even by prolonged washing. If the arsenic exists in in large quantity, a resolution of the arseniate in hydrochloric acid, and reprecipitation by ammonia, is almost always imperative. But, by the addition of cyanide of potassium to the ammoniacal liquid, as described above, until the blue colour disappears, sulphate of magnesia causes a precipitate which can readily be washed free from copper, as the cupro-cyanide of ammonium is far more readily removed than the blue compound. In this case, therefore, two precipitations are avoided. It must not be forgotten, however, that when *iron* is present, as well as arsenic and copper, cyanide of potassium fails to determine the amount of the latter.

Arsenic acid is produced by the solution in acids, arseniate of iron is formed, and this compound being soluble in ammonia, forming a brown liquid, of course vitiates the result. Mr. Parkes proposes the addition of sulphate of magnesia to the ammoniacal solution, previous to the application of the cyanide, by which means the double arseniate of magnesia and ammonia is formed as well as oxide of iron. This mode of procedure I have found to answer very well.

Alloys of *Copper and Zinc*. Cyanide of potassium is valueless for the determination of copper when zinc is present. More of the standard solution is required, the excess depending upon the quantity of zinc which may exist. All kinds of brass, &c. cannot, therefore, be examined by this process for the amount of copper they may contain. When cyanide of potassium is added to an ammoniacal solution of the oxides of zinc and copper, two beautiful crystalline compounds are produced. One of these compounds appears in the form of large light blue crystals belonging to the regular system; the other of snow white needles of great lustre. Both are perfectly insoluble in water, and have not, I believe, been thoroughly examined.

Alloys of *Silver and Copper*. The presence of silver also prevents the estimation of copper. In fact, in an ammoniacal solution of these metals, the cyanide of potassium seems to form compounds with the silver in preference to the copper. Cupro-cyanide of ammonium is decomposed by silver salts. When hydrocyanic acid or a soluble cyanide is added to a solution of a salt of copper in a considerable excess of ammonia, until the liquid is perfectly colourless, the addition of nitrate of silver restores the deep blue colour, and an argento-cyanide of silver, or of silver and copper, is formed. There are a great variety of beautiful compounds consisting of silver, copper, cyanogen, and ammonium, which have not been examined—one especially can be produced by very careful evaporation, in splendid dark blue octahedra, having great lustre, and containing more than 60 per cent. of silver. Another compound separates in pearly scales containing a larger proportion of copper.

Both *nickel* and *cobalt* interfere greatly with the determination of copper by cyanide of potassium.

Manganese and Copper. Mr. Parkes informs us that manganese interferes with the estimation of copper, but its action may be prevented by using the carbonate of ammonia instead of the caustic alkali, and boiling for some time. This may prevent the interference of manganese to some extent, but the results I have always found to be more or less vitiated, and that in a very remarkable manner. It will be observed that in the above solutions of other metals with copper, an excess of cyanide has to be employed, and this is easily accounted for, as the oxides of zinc, silver, cobalt, and nickel, are soluble in ammonia, and thus they exert an action more or less intense upon the cyanogen, preventing that element from combining directly and entirely with the copper. But in the case of oxide of manganese, *less* cyanide is required instead of *more* as with the other metals. Thus, for instance, if 1000 grain measures of solution decolorise 5 grains of copper, 1200 or 1300 are requisite to decolorise 5 of copper with 3 of zinc, or silver, or nickel, but not more than 800 or 900 are necessary to decolorise the same quantity of copper when an equal amount of manganese is present. The free carbonate of potash in the commercial cyanide of potassium precipitates partially the oxide of manganese from its ammoniacal solution, or the result would be still more striking. Two experiments may be cited, one was made upon an artificial compound of 5·00 grains of copper, and 5·00 grains of peroxide of manganese, and the other upon a mineral which I described some time ago in the *Chemical Gazette* a double silicate of manganese and copper, consisting of:—

Water	16·09
Protoxide of copper	27·00
Peroxide of manganese	34·41
Silica	22·16
	99·66

In the first instance 894 grains decolorised the liquid perfectly, no change in appearance took place after some weeks standing. Now, as 1000 grains solution=5·00 copper, 894 grains=4·47 copper, making an apparent loss of more than 10 per cent. of that metal.

In the second case, the numbers seen in the analysis are the result of many careful determinations by precipitation of the copper as sulphide, and estimation as oxide, but cyanide of potassium only gave evidence of 23·8 per

cent. and 23·9 per cent. copper, or about 11 per cent. less than the mineral contained.

I have vainly tried to obtain crystalline ammoniacal cyanides of manganese and copper, an analysis of which might help to explain this phenomenon. It is probable that a colourless compound of these two metals exists; but on evaporation most of the manganese falls as oxide.

In concluding this part of the subject, it may be said that cyanide of potassium is well adapted for the estimation of copper in some few alloys, and for all ores consisting either of copper in combination with various non-metallic elements, or associated with iron, and that the method is susceptible of great accuracy after bestowing the amount of care always necessary in analytical research. Other methods for the estimation of copper will be discussed in a future number.

TECHNICAL CHEMISTRY.

Description of a Patent Blast Gas Furnace, by J. J. Griffin, *F.C.S.*

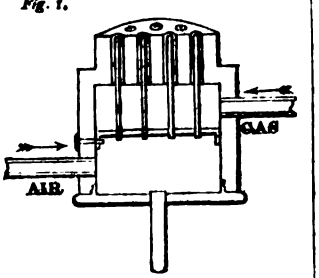
The Patent Blast Gas Furnace consists of two parts, namely, of a particular form of gas-burner, which is supplied with gas at the usual pressure, and with a blast of common air, supplied by bellows or a blowing machine, at about ten times the pressure at which the gas is supplied.

Secondly, of a Furnace, which is built up in a particular manner, round the flame that is produced by the gas-burner, and the crucible that is exposed to ignition. The object of the particular construction of this furnace is to accumulate and concentrate in a focus the heat produced by the gas flame, and to make it expend its entire power upon any object placed in that focus.

This apparatus can be made of various sizes, according to the amount of work which is required from it. We describe below a few varieties of the furnace, and the results of some experiments made with them, which will show the reader what kind of work it is able to execute.

The Gas-burner.—The gas-burner is a cylindrical iron reservoir, containing two chambers, which are not in communication with one another. Into the upper chamber, gas is allowed to pass; and into the lower chamber, air is forced by means of tubes. The upper part of the burner is an inch thick in the metal. Through this solid roof, holes are bored for the escape of the gas. The experiments described hereafter were made with a burner that contained sixteen holes; but burners with six holes, and with twenty-six holes, have been made for other purposes. The number of holes depends, of course, upon the heating power required from the burners. The air passes from the lower chamber, through a series of metal tubes, placed in the centre of the gas-holes, and continued to the surface of the burner, so that the gas and air do not mix until both have left the gas-burner, and then a current of air is blown through the middle of each jet of gas. The bottom of the gas-burner is made to unscrew, and the division between the two chambers, which carries the air-tubes, is easily removable, for the purpose of being cleaned. The gas and air pipes are both half an inch in the bore, and are ten inches long; the gas has usually had a pressure of half an inch of water, and the blast of air about ten times that pressure. The quantity of gas used in an hour was about 100 cubic feet. The stopcock which supplied it had a bore of half an inch.

Fig. 1.



When the gas is lighted and the blast of air is put on, the flame produced by the gas-burner is quite blue, and free from smoke. It is two inches in diameter, and three inches high, and the point of greatest heat is about two inches above the flat face of the gas-burner. Above this steady blue flame there rises a flickering ragged flame, several inches in height, varying with the pressure of the gas. In the blue flame, thin platinum wires fuse readily.

When the gas is burning in this manner, and the apparatus is attached to flexible tubes, the burner may be inverted or held sideways, without disturbing the force or regularity of the flame, so that the flame may be directed into a furnace at the bottom, the top, or the side, as circumstances may require.

The following articles are used in building up the gas furnace for different experiments. They vary in size according to the volume of the crucible, or the weight of the metal which is to be heated.

1. A circular plate of fire-clay, two inches thick, with a hole in the centre, which exactly fits the upper part of the gas-burner, which is made to enter into the hole three-quarters of an inch. In external diameter, this clay plate agrees with each size of furnace.

2. A cylinder of fire-clay, of which two pieces are required to constitute the body of each furnace. In the middle of each cylinder, a trial-hole is made, one inch in diameter, to which a fire-clay stopper is adapted.

3. A fire-clay cylinder, closed at one end, and pierced near the open end with six holes, of half an inch in diameter. The thickness of the clay is immaterial.

This cylinder is three inches high and three inches in diameter.

4. A circular plate of fire-clay, two and a half inches or three inches in diameter, and one inch thick. Similar pieces half an inch thick are useful.

5. A cylinder of plumbago, to be used as a crucible support. It is three inches inside diameter and one inch in height. It is pierced with twelve holes of three-eighths of an inch bore.

6. A similar cylinder of plumbago, two inches high, pierced with twenty-four holes of three-eighths of an inch bore.

7. A thin plate of plumbago, three inches in diameter, namely, of the same diameter as the above three cylinders. It has a small hole in the middle, and being of soft material, the hole can be easily cut or filed to suit crucibles of any desired size.

To suit the larger kinds of crucibles and furnaces, cylinders are made resembling the above in form, but of greater diameter.

As in all cases the heating power of the gas furnace spreads laterally, and does not rise vertically, the most advisable form of the crucibles required for use in it is *short and broad*, not tall and narrow, and the supporting cylinders must be shaped accordingly. No fire-bars or grates can be used to support crucibles in this gas furnace, because no material, formed into narrow bars, can sufficiently withstand its powers of fusion and combustion.

8. A plumbago cylinder, or crucible-jacket, two and a half inches high, two and a half inches in diameter, and

a quarter of an inch thick in the walls. It has six holes of three-eighths of an inch diameter near one end.

9. A circular cover or dome, flanged at the bottom, and having a knob or handle at the top. It is pierced with twenty-four holes of a quarter of an inch in diameter, arranged in two rows near the bottom. This dome, when of small size, is made of plumbago. When of large size, of fire-clay.

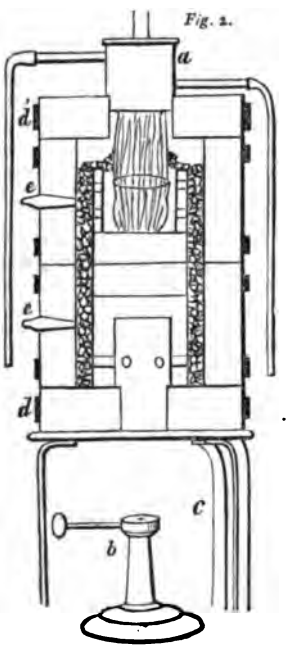
10. Plumbago crucibles made with a solid overhanging rim, the use of which is to suspend the crucibles over the gas-burner, by means of the cylinders, Nos. 5 and 6. When the crucibles are too small to fit the cylinders, the flat plate (No. 7) is filed to fit the crucible, and is then placed on the cylinder, to whose diameter it is adapted.

Besides these pieces of fire-clay and plumbago, it is necessary to be provided with a strong iron tripod, to sustain the furnace; an iron pan, in which to place the furnace; and a quantity of gravel, or rounded flints, not less than half an inch, nor more than one inch, in diameter. These pebbles form an essential part of this gas furnace.

Gas Furnace, heated at the top, exhibited in section by fig. 2.—*a* is the gas-burner (fig. 1); *b* is the support for it, when used below the furnace; *c* is the iron tripod support for the furnace; *d d* are two perforated clay plates (No. 1) adapted to the gas-burner *a*; *e e* are two clay cylinders, like No. 2. These pieces, *a* to *e*, are similar in all the furnaces, and will not require description in each example.

The interior of the furnace, as represented by fig. 2, is built up as follows:—The clay plate *d*, is put upon the tripod *c*. Over the central hole in *d*, the clay cylinder (No. 3) is placed, and upon that cylinder two or three of the clay plates (No. 4). Upon these a porcelain or platinum crucible is placed. If it is of platinum, a piece of platinum foil may be put between the crucible and the uppermost clay plate, to protect the crucible from contact with particles of iron, or against fusion with the clay. The crucible is to be covered by the plumbago jacket, No. 8. The space between this pile in the centre of the furnace and the two cylinders *e e*, which form the walls of the furnace, is to be filled with flint stones, or gravel, washed clean and dried. The stones which answer best are rounded, water-worn pebbles, of half an inch to one inch diameter. These may be piled up to the top edge of the jacket (No. 8). The number of clay plates (No. 4) must be such as to bring the top of the crucible to the distance of two inches, or two and a half inches at the utmost, from the flat face of the gas-burner *a*. In some cases, merely one of the furnace cylinders *e*, is necessary, in which case the crucible and its jacket is placed directly upon the cylinder (No. 3), and when only a moderate heat is required, even the packing with pebbles may be dispensed with. Another means of diminishing the heat is that of increasing the distance between the gas-burner and the crucible.

Fig. 2.



The apparatus being thus arranged, the gas is to be turned on, and to be lighted, the blowing-machine is to be put into action, and the nozzle of the gas-burner is to be depressed into the central hole of the clay plate *d*. The whole force of the blue flame then strikes the crucible; part of it forces its way through the holes in the jacket (No. 8), and part of it rises and passes over the upper edge of the jacket; after which it forces its way downwards between the pebbles. The carbonic acid gas and the vapour of water which result from the combustion of the gas, together with the nitrogen of the air, and any uncombined oxygen, accompany it. No space being left open for the escape of these gases at the upper end of the furnace, they go downwards through the interstices among the pebbles, and passing through the holes in the cylinder (No. 3), and through the central hole in the lower plate *d*, they escape finally into the air. In this progress the hot gases give up nearly all their heat to the flint stones. Water and gases escape below at a very moderate temperature, water even runs down in the liquid state, while the stones rapidly acquire a white heat, and if the blast and the supply of gas is continued, they retain that white heat for any desired length of time — for hours.

At the end of ten minutes after lighting the gas, the crucible, placed in the described circumstances, and exposed to the full action of the heat of the gas, and surrounded by substances which are bad conductors of heat, is raised, with the jacket and pebbles around it, to a white heat. The consequence is, that the full power of the gas jet is then exerted upon the crucible and its contents, and those effects are produced which will be described presently.

If it is desired to inspect the substances subjected to the action of heat in this furnace, the gas-burner is lifted out, and the crucible is examined through the hole in the clay plate. To make it possible to inspect substances at a white heat, the view is taken through a piece of dark cobalt blue glass. If the substances submitted to heat suffer no harm from the action of oxygen, it is better to dispense with a crucible cover, and to direct the jet of flame directly down upon the substance to be heated. The action is then more rapid. When the burner is taken out, the substance in the crucible can be stirred, if it is considered necessary.

The following experiment will give an idea of the power of a furnace of this description. A common clay crucible, three inches high and three inches diameter at the mouth, was filled with about 24 ounces of cast iron. It was mounted as in fig. 2, in a furnace of four inches internal diameter, and eight inches deep. The pebbles were filled in to the edge of the crucible. No crucible cover and no jacket were used. The flame was thrown directly upon the iron. In a short time, the iron melted, the oxygen then converted some of the cast iron into magnetic oxide of iron, which formed a thin, infusible mass, on the surface of the cast iron. At twenty minutes from the lighting of the gas, the furnace was dismounted. The crucible was taken out. A hole was broken by an iron rod in the infusible surface of oxidised iron, and the fused cast iron below it was decanted into a mould, and made a clear casting weighing twenty ounces.

In the same small furnace 32 ounces of copper can be

fused in 15 minutes. When the furnace is hot, that quantity of copper or cast iron can be fused in 10 minutes.

In a furnace of the same dimensions, but with a gas burner having only six, instead of sixteen jets, 16 ounces of copper or of cast iron can be completely fused, in ten minutes if the furnace is cold, and in seven minutes if the furnace is hot.

These experiments show that within twenty minutes a heat is producible in this little furnace which is more than sufficient for the decomposition of silicates by fusion with the carbonates of potash, soda, or barytes.

(To be concluded in our next.)

PHARMACY, TOXICOLOGY, &c.

Chemical Researches on the Essential Oil of Valerian, by M. Pierlot, *Pharmacien.*[1]

In a note presented to the Academy of Sciences, the author had already demonstrated the pre-existence of valerianic acid in fresh valerian root, and had shown the uselessness of the means recommended for developing it in the oil extracted from the plant. He has since examined the oil to discover what principles it contains, and to establish by new experiments that not one of them is capable of becoming transformed into valerianic acid.

The oil of valerian has been made the subject of investigation by several chemists. Among others, Grote, who discovered valerianic acid; Ettling and Kraps, who supposed it to have the same composition as oil of turpentine; Gerhardt and Cahours, who detected in it an oxygenated oil and a hydrocarbon. Lastly, in the seventh volume of the *Annales de Chimie et de Physique*, 1843. Gerhardt published an important article on the subject, and his conclusions have been generally adopted in all recent works on chemistry. In this remarkable work, the author points out some capital errors.

As well as the acid, some chemists have denied the pre-existence of the oil in the plant. According to the partisans of this opinion, the oil is formed secondarily in the same way as oil of bitter almonds. Some experimenters allowing the free access of air, evidently could not obtain the volatile principle. M. Bouchardat having distilled the tincture of the dried root, found neither oil nor acid. The root exhausted by alcohol, treated again with water, and again distilled furnished none; and hence the learned professor concluded that, as these principles had not passed over with the alcohol in which they were soluble, and could not be found in the water, they did not exist in the plant.

The fallacy of the first experiment is seen at once. Alcohol is entirely evaporated at 78° C., while the acid in solution requires 110°, and the oil 120° degrees; and therefore the alcohol passes over leaving these bodies in the residue, where they must be sought for.

That the oil does pre-exist in the plant is proved by the following experiments:—

If one of the radicles is simply crushed on a piece of white bibulous paper, an oily spot is produced.

The distillation of the fresh root with water gives an oil varying in colour, according to the sort of plant used. It is green when obtained from the wild valerian, and yellow when got from the cultivated plant. From whichever obtained, however, its characters do not sensibly differ in other respects. It is very fluid, and gives off a strong penetrating odour like that of the root; its taste is disagreeable, and a little sour; its specific gravity at 10° C. = 0·936. It reddens litmus paper strongly. Exposure to the air removes the greater part of its hydro-carbon, and some of the valerianic acid and water it contains; at the same time the oxygenated oil thickens and is converted into a green resin.

The oil boils at 200° C. A temperature of −40° does not congeal it; but about −150 white flocculi form, and rise to the surface, which, when removed, change to an oily liquid, having the odour of valerianic acid, of which the flocculi are composed.

The oil of valerian does not combine with either caustic potassa or soda.

Cold nitric acid colours it blue; if the mixture be slightly heated, nitrous vapours are disengaged, and at the same time the oil is changed into a blue resin, which is heavier than water, soluble in ether, insoluble in alcohol and caustica potassa, agreeing in these respects with the resin obtained by distilling the oil, and that extracted from the dried root.

When submitted to a simple distillation, the fresh oil gives at from 120° to 200° C. a yellow, oily, limpid, transparent liquid, which is only the oil a little impaired by the operation. This product contains nearly all the acid of the oil; its colour becomes deeper by keeping.

If the heat be raised to from 200° to 300°, a limpid transparent oil of a bottle-green colour is obtained, which is sensibly acid. Exposure to the air, as well as successive distillations, transforms it into a green resin; nitric acid, on the contrary, converts it into a blue resin.

If, after removing the product of this second fractionation, the heat be continued to from 300° to 400°, a thick oily, opaque substance of a greenish colour, passes over containing traces of acid. This is completely changed into resin of valerian by the action of nitric acid.

The two last products, green and blue, mixed and distilled together, give between 200° and 280°, a very fluid, transparent, slightly green, oily body, smelling like hay or the camphor of the labiatæ: this is the *valerol* of Gerhardt. It contains still a little acid. Redistillation renders it colourless, and makes the odour softer and sweeter. Gerhardt calls this *neutral rectified valerol*. It is important to remark that it can only be really rectified by distilling it in contact with a strong base, which will remove the acid it always contains. In this way only we obtain a neutral product which no influence will change into valerianic acid.

During the last distillation, between 200° and 280°, there condenses in the retort tube a crystalline volatile matter smelling like camphor: this is the stearoptene of valerian to which we shall presently return.

Such are the different bodies obtained from the oil, simply by means of heat, and we see that valerianic acid is always present, and is found even in the last products of decomposition.

If now we distil the freshly prepared oil off solid potassa, in a tubulated retort furnished with a thermometer, gradually increasing the heat up to 200°, there passes an almost colourless oil, which smells something like oil of turpentine. At 200° the distillation stops spontaneously. Some aqueous vapour is disengaged, and the oxygenated oil retained by the potassa concretes, and assumes an odour like camphor. The result of this first distillation is the hydrocarbon ($C_{20}H_{16}$) contained in the

[1] Pharmaceutists long ago found out an easier and cheaper way of making valerianic acid than distilling it from the root; but the other products have an interest, especially as one has been recommended for admission to our already encumbered *Materia Medica*.—Ed.

oil. In this operation, which I have often repeated, I have never observed the crystalline matter which Gerhardt sometimes met with; it is only above 210° and at the expense of the oxygenated oil that this body is produced, as we shall see further on. Gerhardt gave the name *borneene* to the hydrocarbon, but I prefer to call it *valerene*. When it is pure it boils at 160°, and evaporates without leaving a residue.

The valerianic acid originally contained in the oil is combined with the potassa; but the oxygenated oil has by no means produced it, as Gerhardt wishes to show.

If now, after having changed the receiver, we continue to heat the oil which was solidified on the potassa, it gradually liquefies, and begins to distil at 210°; boiling directly that temperature is reached. At 280° the distillation stops again, and we have in the receiver a thickish, slightly coloured, neutral oil, containing an abundance of solid camphreous matter, which gives to it a strong smell like hay. This oxygenated oil is the *valerol*.

Exposure to air thickens and resinifies it, but, contrary to the assertion of Gerhardt, does not develope any acid. It is the same with other oxidising agents, such as bichromate of potassa and binoxide of manganese, the influence of neither producing any reaction on litmus

Valerol absorbs a good deal of ammoniacal gas without forming a salt, another proof that it does not contain the acid. It continues to boil from 210° to 430°, showing that it has no fixed boiling point.

The steareoptene of valerian ($C_{34}H_{20}O_8$)—the crystalline camphreous matter which we have found in the valerol—condenses in great abundance in the neck of the retort. At the same time a little water is disengaged, most likely from that part of the valerol which is resinified. There remain in the retort a green resin (C_2H_2O) and some valerianate of potassa, but I have never found this salt in the residue of the rectification of *valerol* over potassa. In the latter case no oxidising agent can produce any other than the elements we have mentioned, viz. the steareoptene of valerian, resin, and water. MM. Gerhardt and Cahours are, therefore, in error when they say that valerol becomes changed into valerianic acid.

The foregoing may be considered as an exact analysis of oil of valerian, 100 parts of which contain:—

Valerene			25
Valerianic acid			5
Valerol	Steareoptene of valerian	18	70
	Resin	47	
	Water	5	
			100

The preceding facts, I believe, prove: 1. That the essential oil *does* pre-exist in the fresh plant; 2. That, fresh or old, it always contains about 5 hundredths of valerianic acid; 3. That rectified over potassa it is perfectly neutral; 4. That it contains two oils: the one a hydrocarbon ($C_{20}H_{16}$) or *valerene*, which is neutral, and volatilises entirely, leaving no residue; the other oxygenated or *valerol* ($C_{34}H_{20}O_8$), also neutral, becoming resinified in the air and by the action of nitric acid, and decomposing into several bodies; 5. That the valerol is composed of the steareoptene of valerian, resin, and water; 6. That valerol cannot be changed into an acid by any (known) process.—*Annales de Chimie et de Physique.*

On a Modification of the Chlorate of Potash method for the Oxidation of Organic Matter in the Detection of Mineral Poisons, by Geo. Thos. Glover.

Of all the processes which have as yet been proposed for the oxidation of organic matter in substances supposed to contain mineral poisons, perhaps none has been found to attain the object more perfectly than that in which the material is treated with powdered chlorate of potash and hydrochloric acid. One very serious objection to this process, however, arises from the large quantity of chloride of potassium, necessarily produced by the decomposition of the chlorate of potash, by the hydrochloric acid, and the subsequent difficulties which we have to encounter, either from the crystallisation of this salt or from the quantity of water required for its solution. In order to overcome this difficulty, I would propose the following modification of the process, which I have found to answer exceedingly well in practice. I introduce into a large flask a quantity of chlorate of potash, about 3 or 4 ounces, in crystals, as I find that when the salt is powdered the action is too sudden. The flask is provided with a cork, through which pass two tubes, one a long funnel-tube to permit of the addition of hydrochloric acid from time to time, and the other bent twice at right angles, in the usual manner, so as to permit of the passage of the gas produced through the liquid to be operated upon. I now pour through the funnel-tube hydrochloric acid, of about sp. gr. 1·05, that is, one part of the ordinary pure concentrated acid and two parts of water. Heat is now applied to the flask, and the gases which come over are passed through the material which we wish to oxidise, and which must be rendered liquid enough for the purpose by the addition of water. I find the process to answer better if the beaker containing the liquids be removed between the renewals of the hydrochloric acid, when the gas has ceased to come, and boiled. The funnel-tube, intended for the addition of the acid, serves likewise as a safety-tube, and must be made sufficiently long to prevent the column of liquid, which will be forced up some height in it by the pressure of the gas, from passing over at the top. This tube likewise, by admitting atmospheric air at the proper time, prevents the liquid in the beaker from being carried back into the flask, an accident which is otherwise rather apt to happen towards the close of the disengagement of the gas. I believe that an india-rubber stopper, provided with holes for the reception of the tubes, such as are manufactured by the Messrs. Macintosh, would answer better for the flask than a cork, being less liable to oxidation. I am quite aware that it has been already proposed to oxidise the organic matter in such liquids by passing a current of chlorine gas through them, but I believe that the process above described will be found much preferable.

Sheffield.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY. *Thursday Evening, December 15th.*

Dr. W. A. Miller *in the Chair.*

A short paper was read by Dr. Moldenhauer, *on the Production of Starch*, in which the author commented upon the arguments derived from the animal and mineral kingdoms in support of the view that the ordinary form and structure of starch granules were to be accounted for by the coalescence of atoms under circumstances antagonistic to their deposition as regularly formed bodies or crystals. Dr. Moldenhauer instanced the transformation of recently precipitated carbonate of lime, which left to itself under water, gradually passed from an exceedingly fine state of division to larger particles, and these eventually assumed the crystalline form of calc-spar; but by rendering the surrounding liquid mucilaginous and more dense by the admixture of

gummy substances, this direction of change was prevented, and small spherules or dumb-bell shaped concretions were now the result of the altered conditions of transformation. The several stages in this and other examples referred to were illustrated by a diagram and by microscopical preparations.

Dr. Gladstone having made a few remarks upon the question generally, and on the explanation of the somewhat analogous shell and bone structures, a passing inquiry was elicited in the course of discussion, as to whether "cohesion" or "gravitation" would be the proper term to apply to the force exerted between neighbouring particles of the same kind of matter.

Professor C. L. Bloxam then gave the results of a very elaborate series of experiments instituted by him for the purpose of ascertaining the capabilities of a system of electrolysis as applied to the detection of arsenic and other mineral poisons contained in organic mixtures. The lecturer commenced his remarks by disclaiming any intention of offering as an original suggestion the recommendation of the employment of the galvanic battery in medico-legal inquiries. He was aware that former attempts had been made in this direction, but not finding such a process in common use, he was led to the present investigation in the hope of being fortunate enough to surmount some of the difficulties which beset such a mode of experimental inquiry. After enumerating the disadvantages of Marsh's test, particularly the consideration that so large an amount of sulphate of zinc, and possibly traces of other metallic compounds, became admixed with the suspected materials, which, in the event of arsenic not being detected, stood in the way of *the same portion* of substance being employed in the search for other poisons, and also to the circumstance that in Reinsch's test copper was necessarily introduced, Mr. Bloxam proceeded to point out the great recommendation of a galvanic system of operating to depend on the circumstance that by its adoption *no foreign metal* nor other chemical reagent capable of affecting the subsequent tests could possibly in this way become intermingled with the suspected liquids. The form of apparatus first employed by him for the detection of traces of arsenic consisted of a U tube holding diluted sulphuric acid, into each limb of which was inserted a small platinum plate connected with the wires of a Grove's battery of five cells. Above the pole from which the hydrogen was eliminated, a cork and hard glass tube, bent and drawn out to a narrow orifice, were adapted so as to allow of the escaping gas being exposed to a high temperature. It having been ascertained that the materials were pure, a small quantity of an arsenical solution was introduced, when it was found that this metal made its escape with the hydrogen and was again deposited as a mirror in the cooler part of the heated delivery tube,—this result following the employment of no more than one-hundredth part of a grain of arsenious acid. A mixture of organic matters was then prepared by macerating together bread, meat, eggs, beer, and milk, with the intention of imitating the undigested contents of a stomach, and to this dark brown liquid the several poisonous compounds were added. The metals included in the plan of examination were arsenic, antimony, copper, mercury, bismuth, and zinc; and of these the two first were evolved with the hydrogen (antimony sometimes, however, being precipitated also as metal), whilst all the others were usually deposited on the platinum plate attached to the negative pole of the battery. These metals could afterwards be dissolved off and separated by digesting the incrusted platinum plate in either yellow sulphide of ammonium, nitric acid, or other convenient solvent, and the ordinary analytical indications of each metal observed. It was remarked that a small quantity of arsenic in the form of its highest oxide was more difficult of detection than when in the state of arsenious acid, and its reduction by means of sulphurous acid was therefore recommended; it was observed also that mercury had the power of masking the indications of arsenic.

Mr. Bloxam exhibited an improved form of apparatus in which his later experiments had been conducted. It consisted of a goblet containing diluted sulphuric acid and a small platinum plate, as the battery terminal, immersed in it; a short tubulated glass cylinder, of about two ounces capacity, with a porous diaphragm of vegetable parchment closing the lower, wide mouth of the same, and also containing diluted sulphuric acid, was placed within the goblet; while its contracted neck was fitted with a cork and hard glass tube drawn out to a narrow jet, and a second platinum plate was suspended within the cylinder in connection with the zinc end of the battery. Such an arrangement would be ready to receive the suspected fluid (poured into the small cylinder), or the product obtained by concentrating to a small bulk the poison contained in the heterogenous matters commonly submitted to medico-legal investigation. A scheme for effecting this separation formed the concluding portion of the paper. Its general features consisted in the destruction of the interfering organic substances by treatment with hydrochloric acid and chlorate of potassa, as recommended by Fresenius and Babo; and afterwards reducing the arsenic acid so produced by means of sulphite of soda. The liquid was then concentrated over a water bath to about one or two ounces, and introduced, with a little alcohol to prevent frothing, into the decomposing apparatus. Along with the hydrogen, arsenic and usually a small quantity of the antimony, would escape, and be deposited again in the heated tube; there was little probability of confounding these two metallic mirrors, for the antimony, less volatile, condensed in the glass tube nearer to the source of heat. The larger quantity of the antimony was however thrown down in company with the other metals on the platinum plate.

In the interesting discussion which followed the reading of the paper, Mr. Alfred Smee stated that he considered that too much stress could not be laid on the advantage of employing a decomposing *force* like electricity, to separate the poisonous metals in preference to analytical systems which required the consumption of large amounts of chemical reagents. The subject of the electro-deposition of arsenic was not new to him, as was shown by referring to some of his published statements regarding that metal. By the employment of a battery of low power, arsenic was reduced to the metallic condition, but with such a powerful apparatus as that employed by Mr. Bloxam he had always found it to be evolved as the hydrogen compound. With regard to the electro-deposition of zinc, he found that the conditions of rough and smooth surfaces would entirely determine whether any metal was reduced, for if in Mr. Bloxam's apparatus a platinised or roughened platinum plate were employed, no zinc could possibly be thrown down, even though a large quantity of that metal existed in solution. Also, if several metals in the same liquid were submitted to electrolysis, particularly where a weak current was employed, they would be deposited in a definite order of succession, and should there be nitric acid in the solution, it would be destroyed before any metallic salt could suffer decomposition.

Dr. Letheby had repeatedly made experiments on various suggested means of applying electricity to the detection of arsenic, but considered the advantages at present as very problematical. When large quantities of all kinds of organic matters required to be reduced to a condition suitable for the application of specific chemical tests, he considered the hydrochloric acid and chlorate of potash system quite inadequate to accomplish the destruction of the great mass of materials then to be dealt with. It was very desirable to limit as far as possible the number and quantity of the chemical agents employed, and he much preferred to employ concentrated sulphuric acid with a little nitric, and by carbonisation of the organic matters, to reduce the bulk of the substances under experiment. There was little fear of losing arsenic by the temperature required to accomplish this; he had actually carried on the process until incineration commenced, without appreciable loss of arsenic. The process he should prefer to adopt in the case of a suspected stomach would consist first, in straining off any insoluble portions, and examining these apart from the rest, and looking in

them especially for arsenic. It should then be digested with alcohol, and this solution decomposed by basic acetate of lead, to effect the separation of the organic acids and other bodies, afterwards discoverable by precipitating the lead by sulphuretted hydrogen, and treating the residue obtained on evaporation with different solvents, ether, chloroform, &c. In this way a poisonous organic substance was sure to be discovered if present, and its effects could be tried on animals, even if the specific name of the poisonous body were not identified. The alcoholic treatment should be followed with water and acids, and these solutions, after destroying organic matter, subjected to a stream of sulphuretted hydrogen; a precipitate, would be sure to form; which when collected could be examined for arsenic and other metals by the ordinary processes. Before the presence of arsenic were definitely pronounced it should be made to furnish both the copper and silver compounds, the reduced metal and the alliaceous odour. Dr. Letheby considered that Reinsch's test could be applied in the course of this examination, for, if the absence of copper had been proved by preliminary experiments, it often afforded a useful indication of mercury and arsenic, which were then sure of detection.

Dr. Odling had great confidence in Reinsch's test, if the proper conditions were secured; he considered, however, that the boiling of the hydrochloric acid solution of arsenic, or the tantamount proceeding of acting with sulphuric acid upon animal matters containing chlorides should be avoided, since this might be attended with the production of a small quantity of volatile chloride of arsenic. In consequence of the action within the system of sulphuretted compounds on any arsenious acid administered, a certain amount of tersulphide of arsenic was likely to be formed, which although but sparingly soluble in hydrochloric acid, was nevertheless sufficiently so for the purposes of detection. He deprecated the practice, in judicial cases, of placing in the hands of the jury a small sealed tube exhibiting a minute arsenical mirror or a microscopic crystalline dust, and contended that the chemist's judgment should be relied upon equally with his experiments, and that a statement of his conclusions should be considered as evidence more impartial than that of trusting the uneducated jurymen to decide upon the nature and contents of the closed glass tube produced in court.

Mr. Bloxam in reply to some of the objections urged in discussion, considered that the sulphuric acid preferred by Dr. Letheby for the destruction of organic matter had all the disadvantages which that gentleman attributed to hydrochloric acid, for this latter was, in the process of manufacture, only likely to be contaminated by the impurities contained in sulphuric acid, and was from its more volatile nature the more susceptible of purification.

Dr. Miller, before moving the adjournment of the meeting, considered that the discussion of a subject of such general interest as that which had just now been brought before them, was likely to prove of the greatest value; and that he wished it emphatically to be understood that the conclusion to be derived from so many phases of opinion as had been expressed that evening, did *not* justify the idea that the indications of analytical chemistry were at all doubtful, or that any difficulties existed in the way of detecting arsenic or other poisons. Such an erroneous impression would be fraught with the most dangerous consequences, if allowed to be misconstrued by the public as being the result of discussion at a meeting of the Chemical Society; for, as all chemists must be aware, we are possessed of most accurate means for their detection and discrimination, and although it is probable that no two operators would follow exactly the same track, there is no doubt that each would arrive at an equally successful result; and it is therefore only a question as to which is *the best* among the many processes at command.

The meeting then adjourned until Thursday, the 19th of January, 1860.

NOTICES OF BOOKS, PATENTS, &c.

A Handbook of Chemical Manipulation, by C. Greville Williams, late Principal Assistant in the Laboratories of the Universities of Edinburgh and Glasgow. Van Voorst: London.

The great progress which has been made in all departments of chemistry of late years, has been owing in no small degree to that fertility of invention, and that scrupulous attention to the most minute details which distinguish the workers in this science. The methods and apparatus of modern chemistry, seem indeed more varied than those required by any of the other experimental sciences. The microscope, the polariscope, the prism, the goniometer, the barometer, the galvanic battery, instruments borrowed from other departments of physics, now render most important aid to the chemical investigator; while in addition, conspicuous improvements have been made in the instruments peculiar to his science, as in furnaces for attaining with ease the highest temperatures, and in gasometrical apparatus.

It is remarkable that while new manuals of analytical and descriptive chemistry are continually produced, no adequate account of modern chemical manipulation was in existence when Mr. Greville Williams's comprehensive handbook appeared. Faraday's treatise on the same subject, full of useful hints and happy contrivances, had then been long out of print, and we may congratulate ourselves on possessing so worthy a successor to it in Mr. Williams's book. Young students not yet initiated into the processes of the laboratory, more advanced workers, and those engaged in original research, will alike find useful information in its pages. The talented author has introduced and described many new processes and contrivances, originated or improved by himself during the course of his investigations. The sections on the use of the balance, on specific gravity, on vapour densities, on filtration, on supports for apparatus, on operations at high temperatures, on distillation, on determination by the burette, and on the manipulatory details connected with organic analysis, are clearly and carefully written. The young student who has not had the advantage of laboratory instruction, will find it easy, by the help of Mr. Williams's descriptions and drawings, to construct any kind of apparatus that he may require. The sections on glass working and on miscellaneous operations will afford to every one engaged in chemical experiment much useful information, the result of long and varied practical experience. There is one feature of the Handbook to which we would direct particular attention, namely, the account of processes and reactions employed in researches, in which the most characteristic and typical answers are given. This is an invaluable boon, especially to those about to conduct original investigations in organic chemistry, and who do not enjoy the constant advice and assistance of an instructor well versed in this branch of the science. It is the first time too that such information has been presented in a systematic and comprehensible form, freed from those specialities which generally accompany the first announcement of any new process or reaction.

Mr. Greville Williams's *Handbook of Chemical Manipulation* is an authority to which we are glad to refer even the beginner, for he will find there concise accounts of the preparation of the more common elementary and compound gases and of the construction and use of the simplest forms of apparatus, and may then become gradually accustomed to technical expressions, to more elaborate contrivances and more recondite processes. It is a book which should be among the works of reference in every public laboratory, and in the library of every chemist. The type is excellent, and the woodcuts, upwards of 400 in number, the best representations of chemical apparatus that have yet appeared in an English work. A copious index, and the tables appended to the volume, enhance its value considerably. We have no redundancies to complain of, and the omissions which we

have been able to detect, are very few and comparatively unimportant, and will no doubt be rectified in a new issue. In taking leave of the Author, we give him our best thanks for his excellent and unique treatise, of which we hope he will have to prepare a second edition before long.

Improvements in Treating and Purifying Gutta Percha. Thomas Cattell, M.D., 12 *August*, 1859.

It is hard to say from reading the specification, what the patentee does with the gutta percha; but it would appear that he first cleanses it by the ordinary process of mastication and washing, and then dissolves it in one of two classes of volatile solvents, in the proportion of 1 part by weight to about 15 parts of the solvent. The two classes of solvents are: 1, those which require the assistance of heat to effect the solution, or, as the specification sets forth, those "whose solventicity bears a ratio and relation to elevation of temperature," such as coal-tar naphtha and its rectified products, turpentine, and other hydrocarbons; and 2, those which easily take up gutta percha in the cold, as bisulphuret of carbon and chloroform. When treated by one of the first class, preference being given to benzole, the patentee adds at the same time the gutta percha and the solvents are brought in contact, one ounce of alcohol holding 30 drops of glycerine in solution to each gallon, or one ounce of alcohol holding 30 grains of soap in solution, or one ounce of pyroxylic spirit holding 30 drops of glycerine in solution, or one ounce of spirit of nitre. The object of this addition is to precipitate the colouring as well as feculent and insoluble matters combined with the gutta percha. The solution is made in a close vessel, heated to about 110° F., and it is then allowed to stand 24 hours to defecate. It is now decanted from the dregs, and is afterwards either exposed for the solvent to evaporate, which is called "the process of congelation," or the solvent is distilled off and saved, or the gutta percha is precipitated from the solution by adding to it an equal measure of alcohol (methylated or not) about 65° overproof, or anhydrous pyroxylic spirit, or fusel oil. In the last case, the mixed fluid is stirred for a few seconds, allowed to stand for a short time, and is then drawn off, leaving the gutta percha ready for use.

The specification does not say what the patentee proposes to do with the mixture of alcohol or pyroxylic spirit and benzole obtained in the last operation.

Whatever may be thought of the process, it seems to answer most perfectly in the hands of the inventor. The specimens we have seen are of the purest white. It may be also drawn in threads, which possess wonderful strength when compared with ordinary gutta percha.

Improvements in treating certain Ores, and in obtaining products therefrom, by William Henderson. 1859.

The improvements relate:

First, to the treatment of zinc ores, or other ores containing zinc:

Secondly, to the treatment of ores of antimony that contain lead, and several other metals:

Thirdly, to the treatment of copper ores:

Fourthly, to the treatment of ores or products containing cobalt:

Fifthly, to the treatment of gold and silver ores and auriferous quartz; and lastly to the dressing or concentrating of lead and other ores.

In treating zinc ores, the inventor first calcines the ore, and then dissolves out the zinc by means of weak hydrochloric acid. If the ore contains much lead, he uses very weak acid. If it contains little lead or copper, he precipitates them with scrap iron or sulphuretted hydrogen, or the lead is separated by sulphuric acid. The zinc is then precipitated as carbonate by continuous boiling with carbonate of lime, and the carbonate is reduced to the metallic state in the usual manner.

In the treatment of the ores of antimony containing lead, and several other metals, the ore is first calcined with a weight of common salt equal to the antimony it contains, air being freely admitted to the furnace; whereupon it will be found that the whole of the antimony, with some arsenic, iron, and other metals, distil over in the state of chlorides. These the inventor condenses by passing them up a tower filled with coke or pebbles, with a small stream of water trickling down. Before, however, they pass up the tower, they are conveyed through a tube, kept at a red heat, into which is introduced a small steam jet. In this way the chloride of antimony is converted into the oxide and hydrochloric acid, which pass on to the tower and are condensed. The oxide of antimony is reduced in reverberatory furnace with charcoal or any other reducing flux; and the metals left after the distillation of the chlorides are reduced by any known means.

The treatment of the ores of copper refers especially to the poor sulphurets. These are first calcined, so as to remove the whole of the sulphur. The copper is now dissolved by means of hydrochloric acid, and afterwards precipitated from the solution by iron. The iron is then removed by caustic lime, and the acid is recovered from the chloride of calcium by a process already patented by the inventor.

To separate cobalt from chloride of iron liquors, the inventor evaporates the neutral solution to dryness; and then converts the chlorides of iron into oxides by means of heat and steam, whilst the chloride of cobalt remains unchanged, and may be dissolved out by boiling water. To obtain the cobalt free from zinc or any of the earths or alkalies, the solution is boiled with a strong solution of bleaching powder, and the black precipitate is washed with dilute sulphuric acid, which leaves the cobalt pure.

Gold ores the inventor divides into two classes, — the first consisting of gold ores properly so called, and the second of auriferous quartz. The first class of ores are smelted (with copper ore if necessary) to obtain a regulus. Two or three tons of this regulus are fused with two parts of anhydrous sulphate of soda and one part coal. When the ore is poor in gold, this mixture must be thoroughly mixed with the melted regulus. After the mixture is made, the heat is continued for an hour or more; the slag is then skimmed off, and the melted regulus tapped into sand moulds in the usual manner. While the pigs of metal are still hot they are thrown into water, which disintegrates them like quicklime, dissolving out the sulphuret of sodium holding in solution the sulphuret of gold. The sulphuret of gold is precipitated from this solution on the addition of a mineral acid to excess, and it is then collected and reduced. The residual copper regulus is used over and over again with fresh gold ore. Auriferous quartz the inventor first calcines and then treats with muriatic acid which does not contain any free chlorine. After standing a few hours, he washes away the muriatic solution until the water is tasteless. He then covers the quartz with aqueous solution of chlorine, which dissolves the gold at once, or at all events in the course of twenty-four hours. Sometimes the inventor mixes peroxide of manganese with the ore before he adds the muriatic acid, and after twenty-four hours he washes out the solution of gold and precipitates the metal by protosulphate of iron.

To concentrate lead and other ores, the inventor simply grinds them in an ordinary corn mill, set so as not to pulverise but only to rub the particles together, and then sifts them through sieves of different degrees of fineness. The first one should be very fine, and from this only ore of the first quality will be obtained, and the inventor finds that the matrix generally leaves the second sieve so poor as to produce ore of no value in a third sieve.

Improvements in the re-working of Compounds of India-rubber and Sulphur, by William Hooper. 1859.

In the manufacture of india-rubber there is a great deal waste. This waste the inventor hardens by heat, and then grinds it to powder, after which he adds a quantity of raw

india-rubber or other substance to make the powder adhere together, and a small proportion of sulphur. He then moulds the compound to any form desired, and heats it to make the hard or semi-hard substance formed by heating such mixtures. By mixing a larger quantity of raw india-rubber with the ground material and employing less heat, a substance something like ordinary vulcanised india-rubber may be obtained.

We should have thought that a plan of this sort would have been followed by every manufacturer of india-rubber.

CORRESPONDENCE.[1]

The Jacob Bell Testimonial.

To the Editor of the CHEMICAL NEWS.

SIR,—No man ever deserved a testimonial more than Jacob Bell, the only question about it can be what form it shall take. A scholarship in the gift of the Pharmaceutical Society must be generally approved of, for the School of the Society may be said to be of Mr. Bell's creation. But if enough money be obtained, I would suggest a plan which would give a wider interest to the testimonial, and would perhaps do more to promote the study of Pharmacy. Let the society offer an annual, biennial or even triennial prize (like the Jacksonian at the College of Surgeons) for the best essay on some pharmaceutical subject and let it be open to the competition of all chemists and druggists. A scholarship has often brought the career of a very promising student to an unsatisfactory close, and the publication of the essay will always prove that the prize was fairly earned. I write this suggestion in the interest of the Pharmaceutical Society of which in most things I am a warm supporter.

M. P. S.

Chemical Notices from foreign sources, by Dr. T. L. PHIPSON.

I. MINERAL CHEMISTRY.

Perchloride of Phosphorus.—M. R. WEBER[2] has shown that a certain number of natural and artificial oxides are decomposed easily by perchloride of phosphorus (PCl_5) with production of corresponding metallic chlorides and oxychloride of phosphorus. Silicic acid obtained by calcination of the gelatinous silica, is decomposed at a red heat by perchloride of phosphorus; a volatile liquid condenses in the recipient. This liquid decomposes water, producing acid vapours and a precipitate of gelatinous silica; it is probably a mixture of oxychloride of phosphorus and chloride of silicium. Stannic acid and titanic acids are decomposed in the same manner.

With alumina oxychloride of phosphorus is formed, whilst near the red-hot tube is condensed a combination of chloride of aluminium with protochloride of phosphorus ($Al_2Cl_3 + PCl_3$). M. Weber has also obtained this combination directly by the union of the two chlorides. It is almost colourless, fusible, and more volatile than either of its constituents.

Chrome-iron, franklanite, spinel, and other minerals are attacked and decomposed at high temperatures by perchloride of phosphorus. The oxides of cadmium, manganese, cobalt, magnesia, and chromium are also transformed into chlorides when slightly heated in PCl_5. With oxide of iron a double chloride $Fe_2Cl_3 + PCl_3$) is formed as with alumina. This double chloride can also be produced by mixing together the two chloroides. Arsenious, iodic, arsenic, and molybdic acids are decomposed by PCl_5 at the ordinary temperature of the atmosphere.

Artificial production of Azurite.—The mineral azurite has for formula $3CuO.2CO_2.HO$. It has been obtained artificially by M. Debray[1] in the reaction of nitrate of copper in solution upon common chalk. The experiment is made in tubes closed at the lamp, and the decomposition takes place at the ordinary temperature and under the slight pressure of three or four atmospheres. The chalk is observed to become covered first with a green matter, which soon transforms itself into crystals of azurite. The following reactions take place:

1st. $3\,(Cu.NO_5) + 2\,(CaO.CO_2) = 3\,(CuO.)\,NO_5 + 2\,(CaO.NO_5) + 2\,CO_2$.

2nd. $3\,(CuO)\,NO_5 + CaO.2\,CO_2.HO = 3\,(CuO),\,2\,CO_2,\,HO + CaO.NO_5$.

The carbonate of lime cannot be replaced by a soluble alkaline carbonate. When bicarbonate of soda is heated in a closed tube with nitrate of copper to 160° (Centigr.) a blue crystalline compound is obtained, insoluble in water, and which is $CuO.CO_2 + NaO.CO_2$. This is the first example we have of a double anhydrous carbonate of copper non-decomposable by water. M. Becquerel produced azurite artificially two years ago by means of electricity. His paper was communicated to the Paris Academy of Sciences.

Peroxide of Lead.—Since peroxide of lead (PbO_2) is employed in the fabrication of lucifer matches, it is prepared on a large scale. Professor Boettger[2] proposes that it should be manufactured by boiling acetate of lead with a clear solution of chloride of lime in excess. In this reaction, peroxide of lead, chloride of calcium, and acetate of lime are formed. The peroxide is washed until it contains no chloride.

This process is only a modification of that of M. Winkelblech, who has shown that salts of lead boiled with an alkaline hypochlorite, produce peroxide of lead. The latter made use of hypochlorite of soda, but chloride of calcium being quite as soluble as chloride of sodium, it is more economical to employ Prof. Boettger's process.

PbO_2 can also be obtained by passing a current of chlorine gas into water, holding oxide of lead in suspension ($2\,PbO + Cl = PbO_2 + PbCl$), or into water mixed with oxide of lead, and an alkali or quick lime ($PbO + CaO + Cl = PbO_2 + CuCl$). It is prepared likewise when oxide of lead is melted with a mixture of chlorate and nitrate of potash.

II. ORGANIC CHEMISTRY.

Cahilose.—M. Payen[3] has submitted to a chemical examination, the substances contained in the birds' nests which are used by the Chinese as an aliment, and form among the Oriental nations the object of a large commerce. These nests, as is well known, are constructed by a species of swallow, which the French term *Salangane*. The quantity of nests exported yearly from the Indian archipelago is estimated at 242,000 lbs. English. The value of the substance is from 100 to 150 francs a pound. In Paris, these swallow nests sell sometimes as high as 400 francs a pound, or 5 or 6 francs per nest. They are sold ready for eating. Many naturalists think that the nests are composed of the spawn of fish, or of a mixture of various zoophytes; others think they are made of a certain juice which exudes from some unknown tree, or that they are constructed with lichens and gelatinous algæ. It appears certain, however, that the swallows produce at the time of nidification a mucilaginous liquid, secreted from their salivary glands, or by the glands of one of their stomachs, in the same manner that the swallows of Europe secrete a viscuous liquid with which they cement together the materials of their nests in the window corners of our houses.

M. Payen's investigations show that such is the case; the agglutinative and alimentary principle of the Salangane's nest sometimes forms the greater part, or even the whole of the nest, and is a peculiar secretion analogous to animal mucus containing nitrogen (9·52 per cent) and *sulphur*, devoid of organisation, sinking in water, and dissolving almost entirely in hot water, taking an orange colour with iodine, soluble in diluted and warm alkaline solutions, &c. To this

[1] As the space we can allow for correspondence is necessarily limited we shall not always be able to publish the letters of correspondents at full length. It will always, however, be our object to give a fair epitome of their contents.

[3] *Comptes Rendus*, Oct. 1859.

new immediate principle, the author has given the name of *cubilose*, which implies the use and natural state of the secretion in question.

Gelose.—M. Payen[1] has likewise given the name of gelose to another principle, which he has extracted from the *Gelidium corneum* or *Java alguæ*, and from a certain commercial substance known as "Chinese moss" (*mousse de Chine*), which is employed in China to prepare jelly, &c. Gelose is extracted from the substances in question by cold water: when dissolved in boiling water the whole is transformed into a jelly on cooling, and in this manner *one part of gelose will transform 500 parts of water into jelly*; weight for weight this new substance has 10 times more gelatinous properties than isinglass. It is insoluble in alkaline solutions, in water, alcohol, ether and weak acids. It dissolves in concentrated sulphuric and hydochloric acids, and forms a brown substance which gelatinises, and resists both hot and cold water, and solutions of caustic alkalies.

Fixation of Colouring Matters.—M. Bolley[2] of Zurich has been studying for some time past, the action of colouring matters upon various tissues, to discover whether their fixation is owing to chemical affinity, capillarity, &c. He appears to have shown that capillarity has nothing to do with the phenomenon, for, amorphous cellulose precipitated from a solution of cellulose in Schweitzer's liquid "combines" with mordants, and with colouring matters (or at least *fixes* them), and can be separated from them again by the ammoniacal solution of cupric oxide. Mr. Bolley has arrived, after various experiments, at the conclusion that tissues fix colouring matters in the same manner as charcoal does, but with less energy. Hence the necessity of employing *mordants*, which form (chemically?) with the soluble colouring principles, *insoluble* lakes which water cannot wash away. The author admits that the mordant is in *chemical* combination with the colour, whilst the latter, together with the mordant, is only *mechanically* fixed upon the tissue as it would be upon charcoal, when precipitated by this agent from a solution. We may observe here, that up to the present time the attraction of charcoal for colouring matters has not been satisfactorily explained.

III. CHEMICAL ANALYSIS.

On the means of detecting sophisticated Milk.—Such is the title of a long paper recently published by M. Delarue[3], of Dijon. The author discusses the value of the various instruments, lactometers, galactometers, lactodensimeter, cremometers, &c. invented for testing the purity of milk, and he shows in a very satisfactory manner that they are perfectly useless and can in no way be relied upon. He endeavours to prove also that chemical analysis is not capable of detecting in every case whether a sample of milk has been sophisticated or not. This may be, for instance, when water has been added to milk which is extraordinarily rich in butter, caseum, &c. Analysis is, however, the only means in our opinion that can be at all relied upon. A sample of milk from the Alps was brought to me a short time ago to be examined. Analysis gave

Water	86·67	
Butter	3·96	solid matter.
Sugar of milk	4·00	
Fixed salts	0·50	13·33 per cent.
Caseum, &c.	4·87	
	100·00	

This result coincides so closely with analysis of good cow's milk cited by Berzelius, Lassaigne, Wöhler, &c. that I did not hesitate to pronounce it of good quality. It would certainly be going backwards were we to depend entirely upon *the taste*, as M. Delarue proposes, in order to test the purity of a sample of milk.

Detection of Arsenic in Organic Matters.—Some discussion has taken place before the Paris Academy of Sciences, as to whether nitric acid and nitrates or sulphuric acid should be employed to destroy the organic matter in a medico-legal search for arsenic. On the 3rd of October last, Mr. Leroy[4] brought forward some facts to show that in Marsh's apparatus arsenic cannot always be detected when sulphurets are present or when sulphurous acid is in the liquid. According to the author these compounds are formed when sulphuric acid is employed; he therefore proposes nitric acid or saltpetre in many cases. On this occasion M. Gaultier de Claubry[2] stated that nitric acid and nitrate of potash cannot be employed as he has shown in his *Traité de Chimie Légale*, that it is impossible to detect sulphurous acid in the black matter resulting from the action of sulphuric acid, although this product (So_2) was admitted to be generally present by Orfila; finally, that it is easy to avoid any error resulting from the production of sulphur spots, or spots produced by metallic sulphurets by adding nitric acid or aqua regia to the decomposed mass produced by the sulphuric acid.

M. Filhol[3], of Toulouse doubts the assertions of M. Gaultier de Claubry, and appears to vindicate M. Leroy's opinions. But MM. Batard and Regnault[4], observe that the question was resolved some time since in one of their reports (1844), in which it was shown that nitric acid and nitrates presented causes of error, and that in most cases sulphuric acid alone could be employed to carbonise the organic matter.

SCIENTIFIC NOTES AND QUERIES.

Gunpowder and its Improvement.—Sir,—In a recent number of the *Daily Telegraph*, the editor, when writing on the subject of gunpowder, hopefully alluded to the time when an ounce might be made to go as far as a pound of the present make. I am afraid we shall have to wait a long time before that will be realised. Many attempts have been made by myself and others in that direction, at a considerable risk. In fact, very strong powders are decidedly objectionable on many grounds; such as the difficulty of making artillery to withstand their action; their extreme danger in handling, and their explosion being likely to recoil with more tremendous effects on those who use them—to say nothing of their unequal expansion and deficient propulsive power or range, as instanced in the case of gun cotton, and compounds of chlorate of potash, with their liability to ignite more readily by friction and percussion than ordinary powder, compared with which the latter is far safer.

The utmost improvement and increase of strength in ordinary powder which can be desired, combined with safety, would be 25 to 35 per cent.; and this I have obtained without the use of any chemical agent, and of which the following example will afford some idea:

Having constructed a target of sound pine wood, free from knots, consisting of eight boards, 1½ inch thick, firmly bound together, Minié balls were fired from a rifle at the distance of 40 yards, the penetration into the solid mass being about 2 inches deeper than with the best government rifle powder, the latter penetrating only the fifth board; whilst mine (or the government powder improved by me) went clean through the sixth and into the seventh board—a pretty strong proof of the improvement effected by the addition of the harmless ingredient alluded to.

But, Sir, the difficulties and prejudices against the introduction of all improvements to the authorities are so great as to deter any inventor, however sanguine he may be of success, from coming forward to disclose his secret and spend his money, unless he is thoroughly satisfied of having a full and fair trial of his invention—disappointment being the common lot of most inventors, notwithstanding the official reports of the trials are in their favour. Trotman's anchor, Prideaux's cooling furnace doors, to wit, *cum multis aliis* that I could mention. The admitted superiority of a thing is not always a passport of its introduction to use; there

[1] *Comptes-Rendus*, Nov. 7, 1859.
[2] *Idem.*
[3] *Idem.*
[4] *Idem.*

are, perhaps, other causes which operate, which the inventors are not supposed to know, or ever can arrive at. In my case, I can fearlessly say that, since the day when gunpowder was first invented, no greater power, combined with corresponding safety, has ever been obtained, or perhaps ever will. Inventors are too often hardly dealt with, and their inventions snubbed and laid aside for awhile dormant, until some one of more tact and cunning re-introduces them under other auspices and other guises and claims the merit of novelty. Indeed, if the statement of the *Engineer* of some few months since be true, as many as 4000 inventions per annum are rejected; whether on sufficient grounds, or not, parties are left to judge for themselves; but so it is—*experientia docet.—John Horsley, F.C.S.*

Cheltenham.

Detection of Metallic Poisons by means of the Battery.—Sir,—In answer to "Medicus," p. 12, I may inform him that Osann has employed a battery for the detection of very minute quantities of arsenic. He dilutes a solution of arsenious acid in hydrochloric acid with water until sulphuretted hydrogen no longer gives a yellow precipitate. He then places a few drops of this solution in a watch glass, and exposes it to the action of a small coke battery. A dark coating of metallic arsenic is soon perceptible at the negative pole. The plan, I have no doubt, might be used in organic mixtures, and would, I think, be superior to Reinsch's method. In the case of arsenic, however, I do not see the advantage of being able to detect such very minute quantities, at all events for legal purposes. Juries, with very good reason, refuse to hang a man on the strength of a few microscopic crystals.—*Expert.* [See also Mr. Bloxam's paper in the report of the meeting of the Chemical Society, which we publish this day.—Ed.]

Note on the Murexide Dyes.—In the process for the employment of the murexide dye for printing, given in the last issue of your journal (page 17), there is a precaution to be attended to which I think of sufficient interest and importance to find a place in connection with the statements of Dr. Von Kurrer. If silk be the material operated upon, and it be printed crimson by the process referred to, there is a great tendency for a certain quantity of mercury, derived from the corrosive sublimate bath, to remain in the fabric as an insoluble compound, and equally impregnating the printed and the preserved white portions of the goods; and will, in the course of time, most assuredly give rise to yellow stains and discoloration—appearing first at the folds, where in packing they are more freely exposed to the sulphuretted contaminations of the atmosphere. An occurrence of this kind having been presented to my notice, I was led to make some experiments, with the view of ascertaining the best method of removing the mercury compound without interfering with the brilliancy of the crimson dye; and in this I succeeded by the use of a final bath of tartaric acid. The goods were passed through a course of treatment similar to that described by Dr. Von Kurrer, for the production of the crimson or rose-red dye, but were found, as I said, still to contain mercury, which no washing would remove; they were then steeped for a short time in tartaric acid solution (8 ounces to 1 lb. of the crystals dissolved in a gallon of cold water), and finally washed. This agent removed from the fabric nearly all the mercury; and the distinction between the state of the goods before and after purification was, on testing with sulphuretted hydrogen, brought out in a very conspicuous manner.

The murexide preparation is supposed to be manufactured from guano: it has a dark red colour, and very much resembles powdered cochineal; the selling price is about 20*s.* per lb. There are also in the market other varieties, of French manufacture, selling at a somewhat higher rate; they are well crystallised, exhibit dichroism, and may be procured in slightly-varying shades of colour.—*John Spiller, F.C.S.*

Chemical Department, Woolwich.

Purification of Water by means of Metallic Iron.—Sir,—In the last number of the Chemical News, in an article on "Why do ships rot?" you state that M. Kuhlmann found that the hydrated oxide of iron "agitated with water, coloured by various organic matters, energetically decolorised it; a fact which led you to suppose that it might be a valuable agent in the purification of waters for the supply of towns." Perhaps you may not be aware that the fact of iron—metallic iron—being a purifier of water is already known. The most impure waters are completely decolorised by the precipitation of all the vegetable and animal impurities therein contained by simple contact with that metal, and by subsequent filtration of the organic matter. Indeed, the principle has been patented, and filters are now being sold which, thanks to chemistry, are not merely strainers, but scientific *disinfectants.—Thos. Salter, F.C.S.*

LABORATORY MEMORANDA.

Coloured Flames.—Bibulous paper soaked for ten minutes in a mixture of 4 parts by measure of oil of vitriol with 5 parts of strong fuming nitric acid, and then washed out thoroughly with warm distilled water, is to be dried at a gentle heat. The gun-paper thus prepared is then saturated with chlorate of strontium, with chlorate of barium, or with nitrate of potassium, by immersion in a warm solution of these salts; a solution of chlorate of copper also may be used. If, after complete drying, a small pellet of any of these papers be made, lighted at one point at a flame, and then thrown into the air, a flash of intensely-coloured light is produced, while the combustion is so perfect that there is no perceptible ash. The barium salt gives a beautiful green light, the strontium-salt a crimson, the potassium-salt a violet, and the copper-salt a fine blue. The chlorates may be prepared sufficiently pure for these experiments by mixing warm solutions of the chlorides of barium, strontium, or copper, with an equivalent quantity of a warm solution of chlorate of potassium. The clear liquid is to be poured off the precipitated chloride of potassium, and employed for the saturation of different portions of the gun-paper. The foregoing makes an admirable lecture-experiment, for illustrating the colours of the barium, strontium, and other flames.—*A. H. Church.*

To determine the amount of Alcohol in Wines and other Alcoholic Mixtures.—Measure off a certain quantity of the liquid, and take the specific gravity and the temperature. Then evaporate half away in the air or in a water bath. Now add water to make up the original quantity, and then take the sp. gr. at the same temperature as before. Subtract the one sp. gr. from the other, and the difference gives the specific gravity of the alcohol and water as they exist together in the wine or mixture. For example—

The sp. gr. of a wine at 50° F. . . .	= 0·9953
After evaporation, and made up with water, it	= 1·0080
The sp. gr. of the alcohol and water .	= ·9873

Spirit having the sp. gr. ·9873 at 50° F. expresses 9½ per cent. of absolute alcohol at 59·5° F., which is, therefore, the alcoholic contents of the wine.—*Mulder's Chemistry of Wine.*

MISCELLANEOUS.

American Platinum.—A new vein of platinum and gold has lately been found at Frederickstown, Mo., by Dr. Koch, of St. Louis. It is stated to be very rich.

Burnishing Paper.—The usual method of glazing paper is by rolling pressure, the webs of paper being calendered between metal and paper rollers. A new method for polishing paper has been introduced by J. Evans, of Hertford, which consists in bringing the paper into contact with sets of polished rollers driven far more rapidly than the surface of the paper. The web of paper is supported during the time it is passing through the calendering rollers by hard polished rollers instead of resting, as heretofore, upon rollers of wood and paper. This appears to be an extension of the calico-printers' and bleachers' method of calendering cloth for the purpose of glazing it.—*Scientific American.*

ANSWERS TO CORRESPONDENTS.

H. L. M.—Charcoal plates for galvanic batteries are made by combining hard charcoal dust (obtained from gas-retorts) with flour paste, then allowing them to dry, and submitting them to a red heat in a closed vessel. Nitric acid is generally employed for them, the same as in Groves, battery. We prefer platinum to charcoal plates.

S. S. Stevens.—A quick-drying varnish for paper or linen can be prepared as follows:—Take gum sandarach, 8 oz.; Canada balsam, 4 oz.; and dissolve them in a quart of alcohol. Varnish made with gum resins and turpentine do not dry so fast as those made with alcohol, but they are not so liable to crack.

Quærere Verum.—1. We do not know one. 2. We should think not. 3. Old name for chlorine. 4. At most instrument makers.

THE CHEMICAL NEWS.

Vol. I. No. 4. — December 31, 1859.

THE BATH-BUN POISONING CASE.

In another column will be found the details of a case of wholesale poisoning, which, coming so soon after the similar occurrence at Bradford, and combined with the prevalent belief with respect to the poisonous adulteration of articles of food, is not unlikely to lead to some rather stringent legislation during the next session of parliament. It fortunately happens that, although several persons were poisoned at Clifton, and suffered dreadfully in consequence, no death has as yet occurred, and if none should take place it may happen that the author of their sufferings may escape unpunished, except from the loss of custom; it is therefore abundantly evident that some enactment should be made to enable the law to reach and inflict an adequate penalty on such offenders as these Clifton tradesmen. The case is certainly the very worst of the kind that ever came to our knowledge. In the Bradford affair there were circumstances which could be urged in extenuation; and the stuff sold for adulteration was, at all events, not poisonous, and unless taken in a large quantity possibly not even injurious; but when a druggist deliberately sells a poison which he must have known was to be used in giving a colour to an article of food, it seems to us that if a person dies from eating it his offence falls very little short of murder in a legal point of view, and is an infinitely worse crime in a moral point of view than merely killing a single individual. It has been suggested that this Clifton druggist was not a *chemist*, but it cannot be supposed that the most ignorant vendor of drugs does not know which of those he sells are poisonous, and in this particular instance there is not the shadow of an excuse of this kind, inasmuch as every preparation containing lead is known to be poisonous, and he must therefore have been aware when he was selling what he supposed to be chromate of lead that he was deliberately selling a substance which must inevitably injure the health even if it did not destroy the lives of several of his fellow creatures, for the sake of the paltry gain of a few pence. It is true that no case is recorded of death having been caused by this particular preparation of lead, but the subject of lead-poisoning has been so recently discussed in all its bearings that it is impossible to allow for an instant that any person who is sufficiently educated to be able to read a newspaper can be unaware that it, in common with all other allied substances, is a poison, and one of the worst kind of poisons too, viz. a slow and lingering one, which, taken into the system, produces effects which may be attributed to natural causes.

We believe that among the vast body of chemists and druggists in the kingdom, it would be difficult to find another beside this Clifton druggist who would wilfully sell poison for the purpose of adulterating food; but we are afraid that it would not be so difficult to find among them men who are not sufficiently careful in selling druggs of this kind; and we would gladly, in the interest of the general body of the chemists, see something done which would insure the observance of greater care. The measures which have been suggested do not appear to us calculated to effect the object proposed; and it would be difficult to point out any that would, without inflicting injustice on some who are entitled to consideration. Making it compulsory on every person who vends drugs to pass an examination at the Pharmaceutical Society as a condition of being permitted to continue his business, might be unjust to many respectable men who have been in the profession for years, and who, though having a good general knowledge of the qualities of the substances they sell, might still be unable to pass through the ordeal of an examination so strict as that of the Society above-mentioned; but it could not be an injustice to a person not yet in business to insist that before he should be allowed to engage in the sale of drugs and chemicals, he should possess a license, in the form of a certificate, showing that he had undergone the test necessary to prove him to be a competent person; and we are strongly of opinion that in future no man ought to be allowed to become a member of the important profession of chemists and druggists without possessing a certificate of this kind from the Pharmaceutical Society. Not only would there be no injustice to individuals in the passing of a bill enforcing this by the Legislature, but the public is fairly entitled to some such precautionary measure being taken; and which, moreover, could not be objectionable to the many highly educated men whose names are to be found enrolled in the list of members of the Society.

We confess we participate to a certain extent in the public alarm, and we cannot deny that there is some truth in the common supposition that the number of cases of poisoning from mistakes on the part of druggists which are discovered, are no criterion of the number of mistakes made. Anybody who is familiar with the poorest parts of London — and no doubt in other great cities it is the same—must have noticed the many dirty, wretched-looking shops, kept by persons who, on the strength of possessing a globular bottle of blue liquid, a poor man's plaster, and a little heap of sarsaparilla or Iceland moss in the window, and a few drugs in the drawers, claim to be considered as chemists and druggists; and not only lay claim to the title themselves, but are actually considered such by the poor creatures who live in their neighbourhood, and who are too ignorant to doubt their medical knowledge. The keepers of such shops as these are not only an injury to the respectable chemists and druggists, on whose education a large sum has been spent in properly qualifying them for the important position they occupy, but they are an imposition on the public. To close these shops by a legal enactment would appear a rather harsh measure towards the proprietors; but short of this we do not see what can be done to protect the public against the repetition of similar cases to that which has called forth these remarks. At all events, we will repeat that no one ought in future to be allowed to practise as a chemist and druggist without having previously passed an examination of the Pharmaceutical Society.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Note on the Existence of Hypobromous Acid, by JOHN SPILLER, *F.C.S., of the War Department, Woolwich.*

IN the course of an experimental determination of the actions respectively exerted by the elements, chlorine, bromine, and iodine upon the nitrate of silver, some few facts presented themselves which appear likely to be useful in more fully substantiating the existence of hypobromous acid.

Firstly, with regard to chlorine. If this gas be slowly passed through a cold solution of nitrate of silver, or freshly prepared chlorine water be brought into contact with the same, this latter being employed in excess, chloride of silver will be precipitated, and at the same time the solution will become strongly acid, and possessed of powerful bleaching properties, due to the oxidation of a second atom of chlorine which remains dissolved in the silver solution as hypochlorous acid. $Cl_2+AgO.\ NO_5=AgCl+ClO+NO_5$. This reaction, originally pointed out by Balard, I have verified more recently by weighing the amount of chloride of silver directly precipitated in that form, and also that subsequently obtained on decomposing the hypochlorous acid in the filtrate with excess of ammonia at a nearly boiling temperature; precipitating then a second portion of chloride of silver by the addition of nitric acid. These two amounts agreed so nearly as to leave no doubt of the truth of the reaction already set forth.

In performing the parallel experiment of adding bromine water to an excess of nitrate of silver solution similar appearances presented themselves. Pale yellow bromide of silver was precipitated, while a considerable amount of a bromine compound remained dissolved in the liquid, communicating to it bleaching properties, and exhaling an odour very similar to that of hypochlorous acid. Quantitative analysis demonstrated that, in this instance also, half the amount of bromine added passed directly into combination with silver, the other half remaining in solution, and existing doubtless in the form of an oxide analogous in constitution to that of the protoxide of chlorine, and to which the name of hypobromous acid (BrO) is applicable.

With iodine, under similar circumstances, a very different reaction is observed. In this case iodide of silver is formed, but unaccompanied by the simultaneous production of a bleaching compound; oxygen is set free, and apparently does not exhibit any tendency to pass on to the state of iodic acid (IO_5), the lowest oxide of iodine of which the existence has been fully established.

The Action of Ozone on some Organic Matters, by M. BESANEZ.

M. BESANEZ has found that on the following substances ozone has no action: urea, hippuric acid, allantoin, alloxan, creatine, leucine, fibrine, gelatine, starch, sugar, inosite, amygdaline, and salicine.

Cyanide of potassium rapidly absorbs ozone, and is changed into the cyanate. Uric acid diluted with water, and agitated with ozonised air, is dissolved and changed into allantoin and urea.

Creatinine is moderately acted on, the products being creatine, and an acid, the nature of which the author will describe hereafter.

The action of ozone on albumen is very curious. M. Besanez hoped to find urea among the protein bodies; but although he directed his attention particularly to this point he was disappointed. Not an atom of the compound was produced, and the author does not believe in the transformation of albumen into urea by oxidation with hypermanganate of potash.

In contact with ozonised air, albumen becomes slightly coloured, and then forms a coagulum somewhat analogous to fibrine, but insoluble in a solution of nitrate of potash. After some time this coagulum liquefies, and when the liquid ceases to absorb ozone, it is no longer coagulated by heat nor precipitated by mineral salts, always excepting the tribasic acetate of lead. By evaporation in a water bath it leaves a brownish residue, which is partially soluble in alcohol. The principal result of this experiment, according to M. Besanez, consists in the formation of a compound similar to that produced when albumen is acted on by gastric juice.

The action of ozonised air on casein resembles the action on albumen. When milk is operated on, the casein is first modified, the fatty matters resist longer, and the lactine is not all affected.

Amylic alcohol acted on by ozone gives first valerol and then valerianic acid.

Oil of cinnamon condenses a large proportion of ozone without being oxidised, but yields it up to substances more easily affected. In this way ozonised oil of cinnamon rapidly decolorises solutions of indigo.

Purified bile is not acted on by ozone: but fresh bile is quickly decolorised, the action being limited to the destruction of the colouring matter, and perhaps also the mucus.

Among the organic substances most eager for ozone is tannic acid. The author has not studied this re-action deeply; but he is certain that oxalic acid is formed, and a body which quickly reduces the cupro-ammoniacal liquid.

M. Besanez, as regards ozone, confirms a fact remarked by M. Chevreul, viz. that the presence of an alkali singularly hastens the oxydation of organic matters. The author also quotes an observation by M. His, who remarked that blood is so completely burnt by ozone that the residue is composed of scarcely anything but mineral substances. M. Erdmann has observed that ozone transforms indigo into isatine.—*Répertoire de Pharmacie.*

TECHNICAL CHEMISTRY.

Utilisation of London Sewage.

THE value of London sewage has been estimated at 3,796*l.* a day, or 1,385,540*l.* a year. Not one farthing of this enormous sum is at the present time realised. On the contrary, we are spending 3 millions of pounds to make the waste more complete and irrecoverable. At the same time we are sending thousands of miles to bring, at great expense, the very materials we waste so recklessly at home. But in a few years the guano deposits will be exhausted; and the supply may any day be seriously interfered with from other causes than the exhaustion of the deposits. It is right then, and indeed imperative, that we should look at home for something to replace guano, and criminal that we should waste the most prolific source of a substitute—the sewage of the metropolis.

The chemical difficulties in the way of extracting the

valuable constituents of sewage are no doubt great. They have been pronounced insurmountable. But a chemist is too apt to assume that what he has not succeeded in doing himself, and cannot at the moment see the way to effect is an impossibility; and he seldom hesitates to say so. In this way Messrs. Hoffman and Witt, a few years ago, discouraged all attempts to extract the valuable matters in sewage by chemical means. It is no wonder then that the Board of Works, which spends without hesitation thousands of pounds on the preparation of plans and specifications, should vote with reluctance a niggardly sum for occasional chemical assistance. This is perfectly intelligible. Miles of tunnelling and mountains of bricks and mortar are easily appreciated by the public who can see no benefit in what would appear to result in no immediate good. The very idea of an experiment is repulsive to them. It suggests an uncertain issue, and all they can see is a certain outlay. It is for these reasons, we suppose, that a Board which employs a staff of engineers to consummate the waste of our sewage has never regularly engaged a chemist to try if the valuable matters in it could not be saved.

Now and then, when a great outcry has been made about some local nuisance, a small sum has been voted, and some gentlemen have been employed whose time was already too much occupied to allow them to do much more than make a report. But the great question is still left in abeyance. It cannot, however, long remain so. Schemes are constantly invented, some apparently feasible, others chimerical and preposterous; and the Board ought at once employ a competent chemist and give him liberal means for testing the value of any reasonable plan which may be proposed. We publish the specification of one to-day, which certainly deserves more attention than it has yet received. It does not completely solve the problem, for it only extracts a portion of the valuable constituents. But so far it is decidedly the best which has been proposed; and actual experiment, on a small scale, has shown that it may be applied to London sewage, with a large daily profit.

Baron Liebig on the Sewage Manure Question.

A LETTER from Baron Liebig to Mr. Mechi, on the subject of sewage manure, has been published in the *Times*. Mr. Mechi, in a letter to the *Times*, a short time ago, insisted on the great importance of the subject to England, and the Baron takes up the matter in support of Mr. Mechi's views:—"It is my ardent wish," he says, "that you may succeed in awakening the English people to your own convictions; for in that case the ways and means for setting aside the difficulties which stand in the way of procuring manure from the sewage of towns, will certainly be found, and a future generation will look upon those men who devoted their energies to the attainment of this end as the greatest benefactors of their country."

The Baron goes on to remark on the constant diminution of productiveness in a soil, occasioned by the loss of those elements which are indispensable to the reproduction of the crops:—"The loss of these elements is brought about by the sewerage system of towns. Of all the elements of the field, which in their products in the shape of corn and meat, are carried into the cities and there consumed, nothing, or as good as nothing, returns to the field. It is clear that if these elements were collected without loss, and every year restored to the fields, these would then retain the power to furnish every year to the cities the same quantity of corn and meat; and it is equally clear that if the fields do not receive back these elements, agriculture must gradually cease."

He then combats the opinion that England will always be able to exchange her coal and iron for corn:—"The time may perhaps come, even in half a century, that not one of those countries upon whose excess England has hitherto drawn will be able to supply her with corn; and that too from the natural law, that what is true of the smallest piece of ground is true also of a great country. It ceases to produce corn, if the conditions of the reproduction of the corn which has been carried off are not restored to it. Nor is it, furthermore, certain whether the corn-growing countries will always desire to exchange their corn for the products of English industry, since they may no longer need these products, or at least in the ratio of England's need of corn. History teaches that not one of all those countries which have produced corn for other lands have remained corn markets; and England has contributed her full share towards rendering unproductive the best lands of the United States, precisely as old Rome robbed Sardinia, Sicily, and the rich lands of the African coast of their fertility. Finally, it is impossible in civilised countries to raise the corn production beyond a certain limit, and this limit has become so narrow that our fields are no longer capable of a higher yield, without an increase of their effective elements by the introduction of manures from abroad."

The Baron then goes on to notice the well-known effects of bones and guano, and after remarking that the high price of bones already forbids their export from Germany, he continues:—

"In relation to guano I have been assured that in 20 to 25 years, if the use of guano should increase in even the same proportion as hitherto, there will not remain in South America enough to freight a ship. We will, however, suppose its supply and that of bones to continue for 50 years, or even longer; then what will be the condition of England when the supply of guano and bones is exhausted?

"This is one of the easiest of all questions to answer. If the common sewerage system is retained, then the imported manures, guano and bones, make their way into the sewers of the cities, which like a bottomless pit have for centuries swallowed up the guano elements of the English fields, and after a series of years the land will find itself precisely in the condition it was before the importation of guano and bones commenced; and after England shall have robbed the cultivated lands of Europe, even to complete exhaustion, and taken from them the power to furnish her longer with corn and manure, then she will not be richer than before in the means of producing corn and meat, but will from that time forth become even poorer in these means.

"It has been maintained that the recovering of the manure elements out of the sewers of large cities is impracticable. I am not ignorant of the difficulties which stand in its way. They are, indeed, very great; but if the engineers would come to an understanding with the men of science in relation to the two purposes—the removal of the contents of the sewers, and the recovery of their valuable elements for agriculture—I do not doubt that a good result would follow. Intelligence, in union with capital, represents a power in England which has rendered possible and practicable things of much greater apparent difficulty."

The letter concludes with a warning:—"I know that the prophets of future evil have at all times been derided by their own generation; but if history and natural laws can furnish any ground for a just conclusion,

then there is none which stands more firmly than this—that if the British people do not take pains to secure the natural conditions of the permanent fertility of their land—if they allow these conditions as hitherto to be squandered—their fields and meadows will, at no distant time, cease to yield their returns of corn and meat."

Description of a Patent Blast Gas Furnace, by J. J. Griffin, *F.C.S.*

[*Continued from page 29.*]

Gas Furnace heated at the Bottom.—In this furnace the parts are the same as those marked *a*, *b*, *c*, *d*, *e e*, in fig. 2; but the gas-burner is in this case put into the bottom of the furnace, instead of the top, and the arrangement of the crucible and its support is altered. Upon the centre of the clay plate *d*, the perforated plumbago cylinder and cover Nos. 5 and 7 are placed; and upon them a plumbago crucible, No. 10. The size of the crucible, and the height of the perforated cylinder, are to be so adjusted that the bottom of the crucible shall be struck by the hottest part of the gas flame; that is to say, the space left between the face of the gas-burner and the bottom of the crucible must not exceed 2½ inches. The crucible is provided with a closely-fitting cover, and pebbles are then filled in between the crucible jacket and the furnace cylinder, and are covered over the crucible until both the pieces of the furnace *e*, *e*, are filled. The gas is then lighted, the blast of air is set on, the gas-burner is forced up into the hole in the clay plate *d*, and the operation proceeds. In from ten to twenty minutes after the gas is lighted—this difference of time depending upon the size of the furnace and the weight of metal contained in the crucible—the interior of the lower cylinder *e*, acquires a white heat. The progress of the operation can be watched by occasionally removing the stone peg in the trial-hole of the furnace cylinder *e*. The heat very slowly ascends into the upper cylinder, and it never becomes so great in the upper as in the lower cylinder. The greatest fusing power of the furnace is confined within a vertical space of about six inches, reckoning from the bottom. The power of flint pebbles to abstract heat from the gases which pass through this apparatus is quite remarkable. When about six inches of pebbles lie above the crucible, and the crucible and the pebbles about it have been white-hot for half an hour, the hand can be held over the top of the furnace, within a few inches of the pebbles, without inconvenience. It becomes wetted with the vapour which rises from the furnace, but feels only a moderate degree of heat.

This form of the furnace is attended by the inconvenience that you cannot examine the condition of the matter contained in the crucible, to ascertain when the heat has been continued long enough. In cases where the fusion is performed repeatedly on the same weight of metal, this would be of no importance, because the power of the furnace is so steady and regular, that the time of firing which has been found to answer once will answer the same purpose again.

When it is supposed that the fusion of the metal submitted to trial is completed, the gas is first to be turned off, and then the supply of air stopped. You can either allow the furnace to remain intact till it is cold, or lift off the cylinders *e*, *e*, with tongs, and allow the hot stones to fall into the iron pan placed below the furnace to receive them. A few bricks should be laid between the pan and the table or stool on which it rests, if the latter is made of wood; because the heat given off by the pebbles is very great. The pebbles being raked away from the crucible, the contents of the latter can be examined.

The absolute sizes of the furnaces depend upon the amount of work required from them. The fusions described below were mostly made in a furnace of six inches internal diameter, a few in a furnace of four inches internal diameter, and one or two in a furnace of eight inches internal diameter; all of them with a gas-burner of sixteen holes, and a supply of gas obtained from a half-inch pipe. A large furnace with an internal diameter of twelve inches, will demand a gas-burner of twenty-six holes, and a supply of gas from a pipe of nearly one inch in the bore.

Examples of Fusions effected by the Blast Gas Furnace.—The fusing points of certain metals have been fixed by Daniell at the following temperatures:—

Silver	1873° F.	Copper	1996° F.
Gold	2016°	Cast-iron	2786°

Brass, with 25 per cent. of zinc, at 1750° F.

All these metals melt readily in the gas furnace. Quantities of 3 lb. of copper or cast-iron can be completely fused in fifteen minutes in a six inch furnace. Quantities of 8 or 10 lb. of copper or cast-iron can be completely fused into a homogenous mass in a six-inch or eight-inch furnace within one hour, using a sixteen-hole burner, and a supply of gas from a half-inch pipe.

In a furnace of the same size I have fused 45 ounces of nickel, and in other experiments I have produced masses of wrought-iron weighing 18 ounces, 28 ounces, and 40 ounces. The piece of 18 ounces was perfectly fused. The piece of 30 ounces was not quite fused, the crucible having melted, and stopped the operation. I have also fused cobalt, and reduced it to the metallic state from the peroxide by ignition with charcoal. The time required for the fusion of these refractory metals is from one and a half to two hours.

Scraps of platinum can be fused into a porous mass, but not into a solid homogenous bead. I have mentioned that thin platinum wires fuse readily in the free flame of the gas-jet produced by the burner fig. 1; but when the jet plays upon a quantity of the metal contained in a crucible the relations of power and effect are different.

When the metals to be melted are such as do not undergo oxidation, the method of action represented by fig. 2 is most convenient. In this manner gold can be readily melted, and by removing the gas-burner the melted metal can be stirred. When the action of oxygen is to be avoided, the crucible must have a cover, which in some cases should be securely luted to it.

Choice of Crucibles.—The experiments above referred to were made with coal gas at the ordinary pressure, and with a blast of cold atmospheric air. Greater effects can be produced by the use of oxygen gas, or of heated atmospheric air. But a difficulty stands in the way of the use of these greater degrees of heat in the want of crucibles capable of enduring their action.

With cold atmospheric air, pure nickel and pure iron dissolve every kind of siliceous crucible, and it is therefore needless to heat the air or to prepare oxygen till a superior kind of crucible is obtainable. At present, these metals can only be melted in plumbago crucibles, which necessarily communicate to them more or less carbon.

Metals which melt at moderate degrees of heat, such as gold and copper, are easily fused either in clay crucibles, or in those of plumbago; the latter, be it remem-

bered, being a mixture of graphite and clay. Metals in combination with carbon, such as cast-iron, also melt readily in clay crucibles, without destroying them. But when such metals as iron, nickel, and cobalt, are freed from carbon, and brought into a state of purity, they acquire an extraordinary attraction for silica at a white heat, so that the metal and the silica readily run down into a very fusible silicate. Even when plumbago crucibles are used, the carbon burns away at some particular point, the metal then attacks the clay, bores a hole through the crucible, and finishes the operation. No kind of clay or porcelain will withstand the action of pure iron or nickel at a white heat. It is therefore impossible to effect any large fusions of these metals when they are free from carbon, or when they are heated in crucibles that are free from carbon.

Fusion of Metals in large quantities and Ignition of Objects of large size.—As the gas-burner, fig. 1, can be held in any required position, it is possible to apply heat to large objects by using several gas-burners. Thus, a large crucible may be fixed in a square furnace, and gas-burners be applied below and on the four sides of the furnace; the spaces between the crucible and the walls of the furnace being filled with pebbles, to collect the heat and apply it to all parts of the crucible.

Muffle Furnace for Assaying, Roasting, &c.—A muffle, placed in an assay furnace, and built up with pebbles, can be heated either from above or from below by the blast gas-burner. The flame and products of combustion can be made to sweep through the muffle, whether going upwards or downwards. The *air* pipe and *gas* pipe attached to the gas-burner, fig 1, must each be provided with a stopcock. When the front door of the muffle is opened to afford the opportunity for examining the cupels, the blast, if continued, would blow out there against the operator; but that occurrence is prevented by turning the stopcocks. When it is desired to oxidise the substances in the muffle, the furnace is first brought up to a sufficient temperature, and then the gas is turned off, but the blast of air is continued. The air passing through the hot pebbles enters the muffle at a high temperature, and then the gas is turned off, but the blast of air is continued. The air passing through the hot pebbles enters the muffle at a high temperature, and not exhausted of oxygen, because there is no carbonaceous matter present among the pebbles when the gas is turned off. The pure and highly heated air is consequently in a proper condition for oxidising metals that are already raised to a red heat in the muffle. The same apparatus is useful where substances require to be roasted in the presence of air, in order to oxidise and expel some volatile ingredient. We have in this process an effectual means of using hot air to aid the process of cupellation.

Distillation per descensum.—Suppose a stoneware bottle with a long neck to be fitted with a stoneware tube, passing nearly to the bottom of the bottle, and projecting some inches beyond its mouth. Suppose this bottle to be half filled with metallic zinc, and then to be fixed upside down in the furnace, fig. 2, with the tube projecting downwards through the hole in the plate *d*, and nearly dipping into a vessel of water. The furnace being packed with pebbles, and the heat applied at the top, the distillation of zinc *per descensum* then takes place.

Miscellaneous Uses of the Blast Gas Furnace.—1. The preparation of chemical substances by the projection of mixtures into a crucible kept at a red or a white heat. 2. For melting silver, gold, copper, cast-iron, brass, bronze, nickel-silver, &c., either for making small castings or ingots. 3. For experiments on glass; every description of which it is able to fuse. 4. For experiments on enamels, coloured glasses, and artificial gems. 5. For experiments on metallic alloys. 6. For the fusion of steel. 7. For the use of dentists, in the preparation of mineral artificial teeth. 8. For the assay of ores of silver, copper, lead, tin, iron, and other metals. 9. For all purposes of ignition, combustion, fusion, or dry distillation, at a red heat, or a white heat, where it is desirable to produce those temperatures promptly, certainly, steadily, conveniently, and cheaply.

Exhibition of Coloured Flames.—When the gas-burner, fig. 1, is supplied with gas and air, and is inflamed in the open air, so as to produce a clear blue flame of 3 inches long, and beyond it a flickering, nearly colourless flame of 12 inches long, brilliant colours may be given to this flame by the introduction of concentrated solutions of certain salts. A ball of pumice-stone, 2 inches in diameter, fastened to a stout iron wire, is dipped into the saline solution, and while wet is plunged into the flame, upon which the whole flame becomes coloured. Solutions of the following salts may be used for these experiments:—

1. *Chloride of Strontium*, gives a brilliant crimson flame. 2. *Chloride of Calcium*, a reddish-orange flame. 3. *Chloride of Sodium*, brilliant yellow. 4. *Chloride of Copper*, bluish-green. If the flame is touched on one side with the copper solution, and on the other with the strontium solution, half the flame is green and half crimson. The colours and reflections of these flames are necessarily most brilliant in a dark room. A remarkable effect is produced by the yellow soda flame. It is reflected from the human countenance with a ghastly blackness.

Repair of the Gas Furnace.—When the clay cylinders become warped or chipped, so as to allow the gases to escape at the joints laterally, they must be luted for each operation by applying a little wet fire-clay by means of a spatula. When only a moderate heat is required, this luting is unnecessary.

The Patent Blast Gas Furnace is capable of melting so many of the refractory metals, and in quantities that are so well adapted for the usual analytical experiments of chemists and assayers, as almost to supersede the use of fixed wind furnaces and portable blast furnaces, fed by charcoal or coke.

On Starches, the purposes to which they are applied, and Improvements in their Manufacture.

Mr. F. Crace Calvert, F.R.S., read a paper on the above subject at the Society of Arts, on Wednesday, December 1st. At the beginning of this century, he said, starch was only used in the laundry, for the toilet, and to a limited extent as diet; but since it and its products have become used in manufactures its consumption has so enormously increased that at one single print works near Manchester more than 300 tons are used annually. In nature starch is often found associated with poisonous matters—in the arum with an acrid substance—and in the mannihot with prussic acid; but the natives of Guiana and the West Indies have found out that by heating the roots of the mannihot the prussic acid is dissipated, and then the tapioca obtained is harmless.

Although the globules of different starches vary in size, and the envelope has a different molecular arrangement to the internal part, still analysis has proved that all have the same chemical composition: viz. C_{12} H_9 O_9 or 72 parts of carbon and 81 of water. With the exception of inuline, all starches give a blue colour with iodine, which disappears when the solution is heated, but returns when it cools. M. Payen has found that by leaving starch in contact with ammonio-oxide of copper for several hours, and then washing the excess of the latter away, and afterwards boiling the green precipitate, a splendid purple will be formed on the addition of iodine, which is comparatively permanent. The globules of starch are found to be composed of successive concentric layers; and M. Payen has observed that these layers have different degrees of solubility in the ammonio-oxide of copper. The outer envelope he found to swell out to 1000 times its original size when in contact with the solution. As extracted from the potato, starch contains 45 per cent. of water, and when stored in a dry place will retain 18 per cent. To distinguish between a starch with little and one with much water it should be placed on a metallic plate heated to 212°, when the former will fly about and the latter agglomerate into hard lumps. Advantage of the last fact is taken on the Continent to manufacture large quantities of artificial tapioca from potato starch.

Starch is converted into sugar by many well known processes, and M. Niepce St. Victor has recently made the curious observation that when paper impregnated with starch is exposed to sunlight the starch is slowly converted into sugar. Starch is also converted into an isomeric substance named glycogene, by the action of the saliva and pancreatic juice. Like flax and cotton, when treated with concentrated nitric acid, it is changed into a fulminating substance called xyloidine.

The starches principally used in commerce are arrowroot, sago, rice starch, wheaten starch, and fecula or potato starch. Arrowroot is only used for food. Sago is extensively used as a substitute for potato starch, either for sizing of warps, or for adulterating other farinaceous substances. Rice starch is obtained by acting on ground rice by alkalies or their carbonates, which dissolves the nitrogenous matter, and liberates the starch. Wheaten starch is found associated with gluten, which was formerly a waste product in the manufacture, but which has recently received a valuble application in calico printing. Mr. Walter Crum has found that under certain circumstances gluten is soluble in weak alkalies, and thus he has used it instead of albumen for fixing on muslins the beautiful colour called French purple.

Starch is usually made by mixing wheaten flour with water in large vats, and allowing it to ferment for several weeks. The fermentation produces what is called *sour water*, which contains alcohol, acetate of ammonia, acetic and lactic acids, biphosphate of lime and decomposed gluten. Alcohol is first formed, but it is rapidly transformed into acetic acid, and it is by this acid and the lactic acid that the separation of the starch and the gluten is effected. The fermentation and the acids, however, do not remove or destroy the whole of the gluten, which forms a layer called alimes or flummery on the top of the starch. This, which was formerly used for feeding pigs, is now employed by the calico printer as a resist paste. After the alimes have been removed by washing and by sieves, the starch is allowed to settle in clear water for several days. It is then drained from the water, dried and cut into lumps of about six inches cubic, which are placed in carefully heated stoves, where they split into the irregular pieces well-known to consumers. Potato starch cannot assume this peculiar form. The foregoing process has been improved upon by Mr. Martin, who kneads the flour into dough, and then washes out the starch, leaving the gluten behind. By this means a larger yield of starch is obtained than by the old process. The gluten is now sold in London under the name of semolina. By adding gluten to flour he also makes maccaroni and other pastes of the same sort. Wheaten starch is extensively used by calico printers for thickening colours in which free acids are employed.

Potato starch is principally made on the Continent by mashing the potatoes, and then elutriating the pulp upon a fine wire sieve, which separates the starch from the fibre. The starch is drained in boxes lined with felt, and then dried on floors of plaster of Paris. To remove the disagreeable taste starch so prepared has, Mr. Martin washes it with a weak solution of carbonate of soda. In addition to the applications before-mentioned, potato starch is extensively used in print works for thickening colours and finishing goods. The Glenfield Company, by mixing a trace of sulphuric acid with the starch, produce an article which forms a clear fluid when boiled with water, in consequence of the conversion of the starch into dextrine. Oxalic acid will effect the same change. Mr. Sorel has shown that a new plastic material capable of replacing, in some instances, ivory and horn, may be made by mixing flour with a solution of chloride of zinc.

When farina is heated to a temperature of 250° to 300° for several hours, it takes the colour of amber, and becomes soluble in water. In this state it is largely used by calico printers. The change which takes place in the heating is only a *molecular* one. M. Payen has shown that the same change may be produced at a lower temperature, by mixing 400 parts of dry farina with 1 part strong nitric acid diluted with enough water to make the farina into a hard paste, which is then dried and heated for 20 hours to 200° F. The product is a farina very nearly white. Mr. O'Neil effects the same result by submitting starch, or any amylaceous substances, to the action of muriatic acid gas or other acid vapours in a cylinder surrounded by steam.

By using a larger quantity of acid, a *chemical* change is produced in the starch, and grape sugar is obtained. This was largely used on the Continent in the preparation of beer. It is prepared by adding farina to sulphuric acid diluted with 33 parts of water, and boiling for 30 or 40 minutes. The sulphuric acid is then removed by means of chalk, and the saccharine solution is evaporated. If the boiling is stopped as soon as the solution gives a purple colour with iodine, *dextrine* is obtained. The same changes are effected by *diastase*, but at a much lower temperature; and it is practically of great importance to know that the action of this body is completely destroyed by raising the temperature to 200° or 212°.

PHARMACY, TOXICOLOGY, &c.

On the Preparation and Properties of Podophyllin.

PODOPHYLLIN is prepared from the root of mandrake (*podophyllum peltatum*), indigenous to various parts of the United States.

It has been stated by some writers that podophyllin contains three principles, viz. resinoid, neutral, and alkaloid. This was a mistake. Pure *podophyllin* is a pure resinoid, composed of two resins, and no neutral or alkaloid principle. In another place we shall refer to these

principles, and demonstrate that such podophyllin is an hydro-alcoholic extract.

Properties of Pure Podophyllin.—Its colour varies according to the mode of preparation, varying from a dark brown to a lemon yellow. It is insoluble in acids; precipitated from its solutions by them; soluble in alkaline solutions; insoluble in cold or hot water, either pure or acidulated; dissolves entirely by alcohol. When its alcoholic solution is evaporated to a syrupy consistence, and mixed with water, all the podophyllin is precipitated, and the filtered liquor is colourless. A portion only is soluble in ether; the insoluble portion is soluble in alcohol. Experiments with the root collected in the spring and autumn give the following results:—

	Podophyllin from the spring root.	Podophyllin from the autumn root.
Resin, soluble in ether	54·34	39·95
Resin, soluble in alcohol	45·66	60·05
Total	100·00	100·00

Properties of the alcoholic extract of Mandrake.—The colour is dark brown; exposed to the air it absorbs water, and becomes soft; is soluble in alkalies: partially so in acids. Water dissolves a very bitter principle, which is probably the so-called alkaloid, and neutral alcohol dissolves it entirely. When the solution is evaporated to a syrupy consistence, and added to water, a portion only is precipitated, and the filtered liquor is highly coloured. Ether dissolves but a small portion, being that portion of the resin soluble in it.

Experiments were made with the mandrake root collected in the spring and autumn, with the following result:—

	Extract from the spring root.	Extract from the autumn root.
Soluble in water	68·65	41·64
Soluble in alcohol	31.35	58·36
Total	100·00	100·00

The portion soluble in water is the bitter principle; that soluble in alcohol are the resins.

Properties of the hydro-alcoholic extract.—The hydro-alcoholic extract has a colour somewhat darker than the alcoholic extract. It attracts moisture more rapidly from the atmosphere than the alcoholic extract; partly soluble in acids; soluble in alkalies; partly soluble in alcohol and ether. When the alcoholic solution is evaporated to a syrupy consistence, and mixed with water, some podophyllin is precipitated.

The hydro-alcoholic extract yields:—

Soluble in water	67·05
Soluble in alcohol	32·95
Total	100·00

Properties of the aqueous extract.—Much darker colour than the last; cannot be reduced to a powder without the addition of some foreign substance; attracts rapidly the moisture of the atmosphere; soluble in acids and alkalies; a portion is soluble in alcohol, but the alcoholic solution does not precipitate any resin; insoluble in ether.

It will be observed that it is not difficult to distinguish *podophyllin* from the extracts of mandrake, for when treated by pure alcohol—if the article is entirely dissolved—it is either *podophyllin* or an alcoholic extract. These are distinguished by the quantity of podophyllin precipitated by water from the alcoholic solution. If the article is not entirely dissolved in alcohol it is an hydro-alcoholic extract. These are distinguished by adding water to the alcoholic solution in the hydro-alcoholic extract that the *podophyllin* is precipitated. In the aqueous extract none will be found.

Pure Podophyllin mixed with Syrup of Milk, Salt, Magnesia, or Powdered Root.—Treat the mixture by strong alcohol till all the podophyllin is dissolved; the foreign substance remains insoluble; filter, wash well with alcohol, and dry. The weight gives the amount of adulteration. To determine the character of the adulteration, we refer to another part of our article.

Alcoholic extract mixed with same articles.—Treat the same as for pure podophyllin.

Hydro-alcoholic extract mixed with same articles.—If the substance is magnesia or carbonate of magnesia, treat the mixture with alcohol, proof or 56°; collect the insoluble residuum on a filter, wash it with alcohol, and dry. Its weight gives the magnesia or carbonate. If the substance is *sugar of milk*, treat the mixture by water, and filter; pass the aqueous solution through animal black, filter, and evaporate to dryness. The weight gives the quantity of sugar of milk. If salt, deodorise by animal charcoal; precipitate the chlorine by nitrate of silver, and use the formula given in the last article.

Aqueous extract mixed with same.—If sugar of milk or salt, proceed as above; if magnesia or powdered root, dissolve in water, filter, and wash residuum well. Its weight will give the quantity of mixture.—*American Journal of Materia Medica.*

Pharmacology of the Mistletoe.

THE *viscum album*, *viscum quercinum*, or mistletoe, belongs to those medicinal agents which probably possess a specific and valuable medical quality, but which, by degrees, have from various causes lost their reputation. According to Pliny, the Druids of Germany considered as holy every oak on which a mistletoe plant grew; and collected the latter with a peculiar ceremony. The plant was worn as an amulet against cramp and epilepsy, and many physicians from that date administered it internally, and spoke highly of its qualities. Colbach affirmed that mistletoe, when properly prepared, stored, and employed with due precaution, cured epilepsy no less certainly than cinchona did intermittent fever.

There can be no doubt that the true *viscum quercinum* of the ancients is the *loranthus Europæus*, a plant which grows upon oak and chestnut trees in southern Europe, and possesses much similarity with the *viscum album*. The latter, however, is smaller, and grows in western and northern Europe on old linden, beech, pear, apple, and hawthorn trees. It is more widely dispersed, and more prolific than the true *viscum quercinum*, but is less active, and therefore a really efficient and valuable medicinal agent fell into disrepute, and was at length forgotten.

It is probable that our *viscum album* possesses similar properties to the *quercinum*, but the truth of the conjecture has not been established by chemical and therapeutical observations. All that relates to the botany of species mentioned, as well as to the chemical characteristics of the *viscum album*, and especially the substance called *viscin*, has been investigated by Henry, Gaspard, Fauke, and others. The curative value of the juice of the berries of the *viscum quercinum* has been examined by Hardy. He mixed one part of the juice expressed from the berries with two parts of melted yellow wax, adding the wax by degrees until an ointment of the proper consistence was formed. This he applied to the

affected part, confining it with a bandage. The application was allowed to remain until the pain moderated, which was usually in the course of a few minutes. Should the pain continue, the plaster may remain a day or more. After its removal the part should be rubbed with oil of almonds. The plaster may be applied to the nape of the neck, in which case it may be allowed to remain longer.

The plaster occasions a violent itching, without reddening the skin or raising a blister. In many cases the patient experiences a slight confusion of intellect, and drowsiness without true sleep; sensation becomes obtuse, and the pain less intense. Fresh plaster need not be used on every occasion, the same being employed many consecutive times with the same effect: moreover, the plaster mass may be kept good for a considerable period if preserved in a well closed vessel.

Hardy has also dried and powdered the berries and used them with good effect with dry friction. He has proved that mistletoe applied in one form or the other always acts as a palliative in cases of pains in the head, spinal marrow, or abdomen.—*Buchner's Repertorium.*

PROCEEDINGS OF SOCIETIES.

PHARMACEUTICAL SOCIETY, 2 Nov. 1859.[1]

T. N. R. Morson, Esq., *President, in the chair.*

A gold medal was presented to Mr. Henry Pratt, of Stratford-on-Avon, for the best collection of British plants. The herbarium was exhibited and fully justified the highest encomiums.

A paper by Mr. H. N. Draper, of Dublin, on "The analysis and preparation of *Granular Citrate of Magnesia*," was then read. The writer's curiosity had been excited by an article sold under the name of citrate of magnesia, which, being in the form of granules and effervescing when added to water, showed that an acid and a carbonate had been mixed together in some unusual way. A careful quantitative analysis showed that the granules were composed of bicarbonate of soda, sulphate of magnesia, and tartaric acid. No citric acid at all was found, and only one and a half per cent. of magnesia. The article was therefore a citrate of magnesia only in name. It had a "terebinthinate odour," for which the author had at first some trouble to account. On reflecting, however, that the mixture must have been made at a high temperature, he thought that some oil of lemon might have been added before the heat was applied,—a supposition which was confirmed when he came to make experiments in imitating the article. He gave the following formula for the preparation of a similar compound:

Bicarbonate of soda	12 oz.	0 dr.
Tartaric acid	10	0
Sulphate of magnesia . . .	2	3
Citric acid	0	5
Oil of lemon	5 drops.	

Rub the citric acid and the sulphate of magnesia to powder together, then add the tartaric acid and bicarbonate, and mix intimately by sifting. Have ready a capsule—preferably of polished copper—set in a water bath, and so arranged that the water vapour shall not come in contact with its contents, and when it has become heated, introduce the mixture into it. After the lapse of a few minutes, the mass will be observed to separate, and it should then be rapidly stirred with a glass or bone spatula until the granula are completely formed. It is then only necessary to keep them from adhering to the sides and bottom of the capsule during the time occupied in drying. Finally, the oil of lemon is added. The operation may be judged to be complete when the granula are perfectly white, and do not feel soft upon pressure under the spatula.

Mr. Haselden then read a paper on the "Miscibility of chloroform, and the so-called chloric ether, with water and other liquids."

The strength of the solution of chloroform in rectified spirit used under the name of chloric ether, is known to vary in different establishments. Mr. Haselden had seen one sample which had one part of chloroform in four of spirit, another was composed of one part of chloroform and nine of spirit; and he had received a specimen from Rome which had only one of chloroform in fifty of spirit. He had made a variety of experiments with the view of ascertaining to what extent chloroform by itself was miscible with water, to what extent spirit assisted, and whether any and what substances interfered with the miscibility, and also to see whether a mixture of chloroform and spirit distilled together was more miscible than a simple solution which had not been distilled. He found that ten minims of chloroform would perfectly dissolve in four ounces of water, if the mixture was well shaken for some time. Ten minims of chloroform with seventy minims of rectified spirit mixed with the same quantity of water without agitation, and the chloroform did not separate. He had kept such solutions a month without observing any separation. Neither dilute acids, tinctures, camphor, gum, nor any substance he tried which was likely to occur in a prescription at all affected the solution. Any stronger solution of chloroform and spirit than the above was found to separate when mixed with water in the same proportions. The distillation of the two bodies together was not found to make any difference in the miscibility. A solution of one part of chloroform in thirty-nine of rectified spirit mixed with water without separation, in any proportion. On the whole, Mr. Haselden believed that a mixture of one part of chloroform and nine parts of rectified spirit (by measure) would be found the most useful for medical purposes, and he hoped a solution of this strength would be introduced into the new Pharmacopœia under a more appropriate name than chloric ether; and he suggested that it should be called *Spirit of Chloroform*. Mr. Squire said that spirit of chloroform was the name that the Pharmacopœia committee had decided on.

A paper on the "Preparation of Pills" by Mr. Tichbourne, Dublin, was then read. The author said that few difficulties the dispenser had to encounter were more annoying than having to form into globular pills a dropsical mass which could never retain its shape a moment—or a hard lump which a pestle and mortar could only grind to powder. Pills composed of various extracts, powders, and volatile oils, were ordered to be made into a mass by means either of soap, conserve of roses, spirit of wine, castor oil, or treacle. To most of these excipients objections might be made. In some cases it was best to make the powders into a soft paste with water, and then to evaporate to a proper consistence, adding the volatile oil towards the end of the process. But what he had found most generally useful in forming pill masses, was a mixture of soap and treacle, made by dissolving hard soap, cut into shreds, in treacle by means of heat, and straining the mixture while hot through fine muslin. Glycerine may be used with advantage in some cases; but when resinous matters enter into the composition, the glycerine sometimes oozes from the mass in tears. This may be prevented by using equal parts of rectified spirit and distilled glycerine. Pil. Cambog. Co. and Pil. Ferri Co., which keep soft, may be made with this mixture. The Pil. Ferri Co., the author said, should be made with the Ferri sulphas exsiccatum; and he suggested that the sulphate was best dehydrated by boiling the powdered crystals in a flask with spirit of wine, keeping the mixture in a state of agitation for a time. The dehydration was completed after boiling 4 or 5 hours, when the spirit might be poured off and the sulphate removed. Pill masses, the author continued, were peculiarly liable to sophistication; and he believed that at least 60 per cent. of

[1] In order that the readers of the Chemical News may be placed in possession of a complete record of the meetings of this Society during the present session, we now give an abstract of the meeting which took place previous to the publication of our first number.—Ed.

those sold were spurious. The blame, he considered, rested partly with the scientific prescriber, who sometimes ordered expensive drugs with no particular therapeutical object (*e. g.* saffron in Pil. Aloes c Myrrhâ): but much more attached to the retail druggist and compounder, who, for the sake of a little extra profit, induced the manufacturer to furnish an article at a less cost than the genuine could be produced.

Mr. Squire said blame in the matter was out of the question. The remarks of the author probably applied to what was sold in Dublin. The meeting then adjourned.

NOTICES OF BOOKS, PATENTS, &c.

The Causation and Prevention of Disease, by John Parkin, *M.D.* Churchill: 1859.

Of the chemistry of morbific poisons in general, very little is known — of those concerned in the production of cholera and fever we know nothing at all. They have hitherto defied all the efforts of the chemist to isolate them. One day, no doubt, the analyist will seize on them, and exhibit their physical conditions, and explain all their chemical relations, but that day is probably far distant; and with our past experience, that poisons are discovered ages before antidotes are found, we can hardly wish a speedy success in wringing from Nature her fearful secret.

In the meantime if we know nothing of the poisons themselves, we do seem to know something of the conditions under which they are generated, and the circumstances which appear to promote their action. And yet so glaring are the contradictions obtained when these conditions and circumstances are investigated, that the seeker after truth without a theory to support, hesitates a long time before he draws any general conclusion, and perhaps altogether abandons the attempt to do so. We cannot wonder then that Dr. Parkin refuses his assent to the common opinion which refers the production of cholera and fever to the decomposition of animal and vegetable matter, to overcrowded dwellings and towns, or to the use of impure water. He reads that the Kamtschatkans live upon and among putrid matter for more than half the year, and that six families of them with all their provisions for the period, are crowded into one small underground cabin, and yet suffer from nothing but scurvy. He finds that in the knackers' yards at Montfaucon, where the flesh of the animals slaughtered is allowed to putrefy for manure, and where the stench is the most horrible that can be conceived, the men and women regularly employed say they are never ill, that they have all the appearance of perfect health, and are known to be long-lived. He is told that occasional workmen suffer no ill effects, nor does an infant "whose cradle during the hours of labour was the carcase of a horse." Decaying vegetable matters seem to be quite as innoxious. The suffocating stench in a ship freighted with sugar, was never known to generate disease, and the emanations from flax are quite harmless, when it is macerated in a house.

Nor are the *known* gaseous products of decomposition, taken separately, capable of producing cholera or fever. Carbonic acid, nitrogen, sulphuretted hydrogen, carburetted hydrogen, phosphuretted hydrogen and ammonia, will all kill when respired in sufficient quantity, but do not produce specific diseases. Sulphuretted hydrogen has been supposed to be the fever miasm, but if it really were so, what student of chemistry would escape the disease? But Dr. Parkin is quite in error when he says that we are well acquainted with all the products of the decomposition of organic matter. If he had ever attempted to analyse the gases evolved from decomposing sewage, or those obtained from Thames water by boiling, he would have found more than the gases he has enumerated above. There is, for instance, that inexpressibly fœtid *something* which gives the characteristic stench to sewers and drains. We do not say that this is *the* poison, but every medical man must have had cases in which a patient has caught the smell of an open drain in passing along the street, and has almost immediately been seized with sickness and diarrhœa. Whatever it is, however, it cannot yet be separated. It goes with the carbonic acid when the latter is removed by means of potash, which seems to show that it may be an organic acid.

Again, in collecting the ammonia from Thames water or sewage by distilling into dilute hydrochloric acid, we obtain a solution which, evaporated carefully to dryness, leaves a bright yellow residue, evidently containing something more than chloride of ammonium. We mention these things only to show Dr. Parkin that all the individual products of animal and vegetable decomposition are not yet known; and that there are many more compounds formed than the gases he has mentioned.

We cannot enter into the question as to what may be the poison of malaria, which is usually assumed to be the product of vegetable decomposition. Whatever it may be, it is proved to be without smell, and must be insoluble in water, although aqueous vapour would appear to be the carrier.

The theory of vegetable decomposition Dr. Parkin rejects, but has his own explanation which we give in his own words. "The process which produces malaria must take place beneath, not above, the surface. Now there is only one process that takes place beneath the surface, and which gives rise to the production of poisonous elements, independently of the decomposition of organic matter; and that process is what has been termed volcanic action." And again: "all general and specific diseases, or in other words epidemics and endemics are due to the extrication of a gaseous substance from the interior to the exterior of the earth."

And now for the cure. As there is no possibility of extinguishing those subterranean fires, it would seem to be a hopeless business; but Dr. Parkin consoles us with the assurance that we have efficient remedies at our hand on the surface of the earth. We must pave our towns to render the extrication of the morbid agent impossible; embank our rivers, so that the surface may always be covered to low water mark, thoroughly drain our marshes, or if that be impossible, flood them. Where neither of these things can be done, strew the ground with fresh burnt charcoal to absorb the poison as it rises; and if this be not possible, light fires and develope carbonic acid, which "is a certain antidote."

In conclusion we have to thank Dr. Parkin for a well-written, interesting, and suggestive book; but we feel bound to correct a mis-statement in the appendix. He says that "the quantity of organic matter contained in the sewers is utterly insignificant when compared to that which the Thames holds in solution." How then can he account for the fact that water taken from the middle of the river at Isleworth, which could not be affected by London sewage, contained only 1·17 grains of organic matter to the gallon, while that taken in the middle of the river at London Bridge about the same time contained 6·85 grains to the gallon? It is unfair also to take the contents of the Earl sewer as a fair sample of London sewage. If Dr. Parkin had looked further along the table, from which we imagine he quoted, he would have seen that the Northumberland Street sewage contained 88·76 grains of organic matter in the gallon, and that the Savoy Street sewer had on one occasion as much as 108·48 grains in the gallon.

An Improvement in the Manufacture of a Manure from Sewage Waters, and other Fluids containing Ammonia or Nitrogenous Matter. G. L. Blyth.

It is well known that the valuable constituents of sewage are the phosphates, ammonia, and the organic matters it contains. Mr. Blyth's invention consists in precipitating the phosphates, a large percentage of the ammonia, and all the insolublé organic matters, by means of a soluble or super-phosphate of magnesia. "When super-phosphate of magnesia is added to sewage it neutralises the ammonia, forming

an insoluble triple phosphate of magnesia and ammonia, which is precipitated or thrown down out of the liquid. If sufficient ammonia be present in the sewage to neutralise the whole of the super-phosphate added, it is all precipitated and carries with it all the insoluble and nitrogenous matters held in suspension in the sewage; but if the sewage has not undergone such decomposition so as to give rise to the formation of ammonia, then it will be necessary to add some other alkali, as, for example, lime in sufficient proportion to neutralise the whole of the excess of acid, which kept the super-phosphate in a soluble state. The precipitate is a valuable manure, while the supernatant liquor, being freed from ammonia and nitrogenous matters, liable to undergo putrefaction, becomes deodorised, and may be applied either to the irrigation of land, or run off into the ordinary channels of drainage without fear of creating any nuisance or offence."

The super-phosphate of magnesia the inventor prepares by the mutual decomposition of the super-phosphate of lime (prepared from bones, bone-ash, apatite, coprolites, &c.) and a salt of magnesia. A given proportion of this super-phosphate is mixed with the sewage, and if it remains acid sufficient lime is to be added to render the whole alkaline. The mixture is now violently agitated for a few minutes, and the result is a curdy precipitate which quickly subsides, carrying with it, as a clarifier, all the insoluble matters which may have been held in suspension.

One great advantage this process has over most others which have been invented, is that the matter added to the sewage is in itself a valuable manure.

The great obstacle to the profitable treatment of sewage is the excessive dilution—the excreta of each individual being mixed with about 23 gallons of water, exclusive of the rain fall. In this state, however, one experiment made with this process gave a deposit containing 4·5 per cent. ammonia, 3·66 per cent. of phosphates, with 58·11 per cent. organic matter; a result which, if constant, would yield a fair profit on the working. The Metropolitan Board ought to give this process a trial on a liberal scale.

CORRESPONDENCE.

Chemical Notices from Foreign Sources, by Dr. T. L. Phipson.

I. MINERAL CHEMISTRY.

New Carburetted Hydrogen.—At the last meeting of the *Société Philomatique* of Paris, M. Berthelot[1] announced that he had discovered a new gas, which he calls quadricarburetted hydrogen, and which is represented by the formula, C_4H_2. This gas is produced by the decomposition of alcohol and ether at a red heat. Its properties resemble for the most part those of olefiant gas. The author will describe them in detail as soon as he has succeeded in obtaining this new gas in a perfectly pure state, as well as the various compounds to which it gives birth.

Oxysulphuret of Antimony.—M. Jacobi[2] has made known in France the art of preparing and preserving oxysulphuret of antimony according to the Prussian pharmacopœia, which gives a receipt for a very fine product.

1500 parts of ordinary carbonate of soda are dissolved in 7500 parts of water; and to this solution are added 500 parts of lime, rendered semi-liquid by the addition of 1500 parts of water; to this mixture 100 parts of black sulphuret of antimony are added together with 125 parts of sulphur. The whole is boiled for an hour and a half, water being added now and then to replace that which is evaporated. The residue is again boiled with 3000 parts of water, the solution is then filtered and the filter washed with warm water. The liquid is allowed to rest, and the crystals obtained washed with distilled water, to which $\frac{1}{100}$ of potash is added, they are then dried. 500 parts of these crystals are dissolved in 2500 parts of water, the solution filtered and diluted with 12,500 parts of water. To this is added a mixture of 150 parts of sulphuric acid with 4000 parts of water. The precipitate formed is collected on a filter, washed first with ordinary water, then with distilled water, pressed between folds of blotting paper, dried at a temperature of 77° Fahrenheit, reduced to powder and preserved in a black bottle removed from the light. The drying at a low temperature, and the washing with distilled water, are two important conditions whereby the preservation of the product is assured.

Aluminium.—It will be perhaps interesting to notice here two new applications of this useful metal. The first is a chemical balance, entirely constructed in aluminium by MM. Collot frères of the Rue de l'Ecole de Medecine, the first of the kind ever produced. The second is the artificial arm of our excellent tenor Roger. It will be remembered that whilst out shooting M. Roger met with an accident which caused him the loss of his right arm. An artificial arm in aluminium has been made for him, the mechanism of which, constructed by M. Mathieu, is so perfect that every movement, every posture is easily practicable, and with the best opera-glass it is no easy matter to distinguish between the natural and the artificial member. M. Roger made his *rentrée* at the opera a few nights ago before a most enthusiastic assembly, and never was a more brilliant success achieved. When Wöhler first extracted aluminium in small globules from the chloride, he little thought that it was destined to play such a part upon the stage.

II. ORGANIC CHEMISTRY.

Tartaric Acid, Natural and Artificial.—A few months ago, M. Liebig, discovered a means of obtaining tartaric acid artificially, by the action of nitric acid upon sugar of milk, gum, &c. On that occasion M. Biot remarked how interesting it would be to determine whether the acid formed artificially had the same optical properties as the natural acid, which acted upon polarised light in a very peculiar manner. M. Bohor, in a short letter to M. Pelouze[3], has just shown that a solution of the artificial acid has precisely the same optical properties as a solution of the acid obtained from grapes or other fruits. The plane of polarisation is deviated *to the right* by both solutions; the succession of the coloured images when an analyser is affixed to the apparatus is the same for both acids; finally, both acids show the same peculiarly large deviation of the plane of polarisation, when they are mixed with a very slight quantity of boracic acid; a fact discovered by Biot, who observed, many years ago, that a trace of boracic acid added to a solution of tartaric acid caused an enormous increase in the deviation alluded to, and this phenomenon appears to be characteristic.

Oxalic Acid obtained from Chlorides of Carbon.—The production of oxalic acid by the action of sesquichloride of carbon upon an alcoholic solution of potash, was mentioned by M. Berthelot, in the *Annales de Chimie et de Physique*, 3e série, liv. p. 87. M. A. Geuther, has lately published a note upon the same subject. When a mixture of sesquichloride of carbon C_4Cl_6 and pulverised hydrate of passia (1 eq. of the first for 8 eq. of the second), is heated for some days in an oil-bath to 210° or 220° (Centigrade), there is formed a mixture of chloride of potassium and oxalate of potassa without any other product:

$$C_4Cl_6 + 8KO.HO = 2(KO.C_2O_3) + 6\,KCl + 8\,HO.$$

When 1 equivalent of protochloride of carbon $C_4\,Cl_4$ is heated for some time to 200° (C.) with at least 6 equivalents of pulverised hydrate of potash, oxalate of potash is likewise formed, and hydrogen gas evolved.

$$C_4Cl_4 + 6\,KO.HO = 2\,KO.C_2O_3 + 4\,HO + 2\,H.$$

Synthesis of Oxygenated Bases—Artificial Alkaloids.—M. Wurtz[4] has shown recently, that oxide of ethylen can be united directly with water, and form mono-

[1] *L'Institut*, 21 Décembre 1859.
[2] *Journal de Pharmacologie*, Bruxelles, Novembre 1859.
[3] *Comptes-Rendus*, 5 Déc. 1859.
[4] *Annalen der Chemie und Pharmacie*, cxl. p. 174.

ethylenic alcohol (glycol) diethylenic and triethylenic alcohol, according as these combinations take place between 1, 2, or 3 atoms of oxide of ethylen and 1 atom of water,

The same author[5] now makes known that oxide of ethylen will unite with ammonia without elimination of water; that is, all the elements of oxide of ethylen combine with all the elements of ammonia and form oxygenated bases remarkable for their energetic properties. To prepare them, oxide of ethylen is added to a concentrated solution of ammonia, and the mixture left to itself. If care be not taken the whole explodes with a powerful detonation, for the reaction produces much heat. When the experiment is conducted properly a syrupy alkaline matter is obtained. This is neutralised with hydrochloric acid, and the solution, sufficiently evaporated, produces colourless rhombohedric crystals which contain:[6]

$$C_6H_{15}NO_2, HCl.$$

A solution of these crystals forms a double salt with chloride of platinum. The supernatant liquid from which the crystals in question have been deposited contains another chloride, which cannot be crystallised, but which gives also a double salt with chloride of platinum.

The first platinum salt contains the elements of 1 atom of ammonia and 3 atoms of oxide of ethylen; the second platinum salt contains the elements of 1 atom of ammonia and 2 atoms of oxide of ethylen.

We have therefore two new oxygenated bases:

1st. $2C_2H_4O + NH_3 = C_4H_{11}NO_2$

Oxide of ethylen,

2nd. $3C_2H_4O + NH_3 = C_6H_{15}NO_3$

which in the state of chlorides combine with chloride of platinum, as chloride of ammonium, of potassium, &c., do. There seems to be no reason why compound ammonias should not react in the same manner; and the above furnishes us, doubtless, with reactions which will become a fertile source of artificial oxygenated alkaloids; moreover, they seem to confirm an idea conceived by Berzelius, that alkaloids contain ammonia already formed.

III. CHEMICAL ANALYSIS.

To discover Mercury in Milk.—When mercury is contained in milk in very slight quantity it is difficult to demonstrate the presence of this metal.

M. Personne[7] has recently made known a process by which traces of mercury may be distinguished in the above liquid. A current of chlorine gas is passed into the milk until all the casein is separated, the liquid is then filtered and the excess of chlorine removed by sulphurous acid or by a sulphite; the mercury is then precipitated by hydrosulphuric acid, the operation proceeding slowly and in a corked bottle. The precipitate obtained is washed by decantation, collected in a small capsule and dried in a water-bath. It is then introduced into a tube and covered with lime, the tube being bent U-shaped. This little apparatus is then heated to redness, beginning at the lime and finishing with the precipitate. The characteristic reaction with a blade of gold can then be made, the amalgam obtained being decomposed by heat.

SCIENTIFIC NOTES AND QUERIES.

Syrup of Iodide of Iron.—Sir,—In answer to *B. C.* p. 24, I can say that pretty much the same thing happened to me once with a strong solution of iodide of iron which I prepared. I made my solution with iron filings, and I am inclined to think that they must have had some brass filings among them. I believe that it is a subiodide of copper which is held in solution by the iodide of iron until the solution is diluted. I threw away my solution, and would recommend *B. C.* to do the same with his syrup, unless he feels inclined to make a good analysis of it.—*Pharmaceutist.*

[5] *Comptes-Rendus*, 5 Décembre 1859.
[6] C=12, H=1, N=14, O=16.
[7] *Journ. de Pharm.* Bruxelles, Oct. 1859.

Purification of Water by means of Oxides of Iron.—Sir,—In the first article of your second number, I observe the following:—"But M. Kuhlmann's paper also suggests that the destructive action of the sesquioxide may be employed for a very useful purpose. He found that the hydrated oxide agitated with water, coloured by various organic matters energetically decolorised it; a fact which leads us to suppose that it might be a valuable agent in the purification of water for the supply of towns. To this part of the subject we intend to return on an early occasion." Perhaps you will not deem it out of place if I take this still earlier occasion of informing you that I have publicly applied the oxide of iron to "the purification of waters for the supply of towns" since 1857, the experiments for which were known to be made long before.

I also claim to be, to the best of my knowledge, the first who gave public expression to the idea of the use of oxide of iron in connection with the purification of water and some other bodies.

It is at the same time impossible for me to know what private "laboratory notes" do exist, which read *now*, may appear suggestive of the same thing, but which very often do not see the light until after the practical accomplishment of the facts to which they are supposed to refer. Nor have my investigations and practice been confined in the same course to oxides of iron alone, as my publications show.

I may further mention that my patents in reference to the purification of water and several other bodies by these means have been translated and in print in France and Germany for nearly two years; the subject, therefore, is not necessarily a new one to M. Kuhlmann.

Allow me to add in reference to the practical value of his paper (as I read it in your translation) that every one in this country practically acquainted with shipbuilding, and many that are not, are fully aware of the extent of the destructive action of iron bolts and fastenings on the timber of ships. Certainly, the people at "Lloyds'" are, if none else. Were this circumstance not well known, should we so often see vessels advertised as being "copper bolted and fastened"? On the other hand, destructive as iron is known to be under these circumstances (M. Kuhlmann must have examined very extreme cases), yet where its effects pervade the timber, it is, so far, a check to that greater destructive action—dry rot.

I may say in conclusion that M. Kuhlmann seems to be in error with regard to the primary nature of the action of these oxides on timber.—*Thomas Spencer.*

P.S.—I had almost forgotten to say that a sesquioxide of iron, even when "hydrated," is an impracticable purifier of water.

On the detection of Arsenic in Criminal Cases.—Sir,—Circumstances irrespective of the late trial of Smethurst having directed my attention to the object of the detection of arsenic, I have learned some facts which may perhaps be useful to the medical and legal professions in future cases of poisoning by that substance.

It will be in the recollection of your readers, that a considerable discussion arose out of Dr. Taylor's use of the wire gauze in the detection of arsenic after Reinsch's test, which by immersion for a longer or shorter period, according to circumstances, in any liquid supposed to contain arsenic, and acidified with hydrochloric acid, becomes coated with a steel-like crust of other metal, possibly either arsenic or antimony, for both give similar deposits; but although, as I have proved, the sensitiveness of Reinsch's test is such as to enable us to detect the *millionth* part, equal to a grain diffused through as many as 15 gallons of water, *when we know it to exist* or to have been put there, yet its only use is as a *kind of guide* for further operations with a view to determine the precise nature of the matter—its actual quantity being afterwards ascertained by other means.

Sensitive, however, as Reinsch's test may be, it applies more particularly to arsenious acid and its compounds. Arsenious acid, commonly known as white arsenic, is an oxide of the metal arsenic, consisting of 1 equivalent or proportion of arsenic and 3 of oxygen, and is only sparingly soluble in water, but when searched for by Reinsch's test (if it exist at all) it may be expected to show itself on very bright copper in from 5 seconds to as many minutes, according to the quantity contained.

But it is otherwise with *arsenic acid* and its compounds, which differ from arsenious acid in that they are not only more highly oxidised substances, containing nearly twice as much oxygen, but are *far more soluble and virulent in their effects upon animals*; and it is in consequence of this oxidisement that a layer of metallic arsenic is not *so readily* obtained by Reinsch's test as with arsenious acid and its preparations, that many persons,

failing within a certain time to detect its presence, may be disposed to put *a negative* construction upon it, when the poison may exist there to a greater extent than they are aware of, and by continuing the operation or adopting some other method it can be easily found.

In Smethurst's case it was put forward as a new theory that because arsenic was found in one instance, and not in another, the chlorate of potash (also found in the liquid) must have interfered in such a way as to have prevented its detection—nay, I should rather have said, *its precipitation by Reinsch's copper test only.*

Chlorate of potash, by its oxydising tendency, certainly does hold up the arsenic in solution, as well as corrode the copper, to such an extent as to impart a strong green colour; nevertheless if arsenic exist at all, it may be detected by the evaporation of the green liquid to absolute dryness, mixing the resulting brownish red-coloured residue with powdered charcoal in a test tube, and submitting it to a strong heat, when the arsenic ought to show itself inside the bottom of the glass, on cooling, as a white saline crust.

If this crust be boiled with a sufficient quantity of water, so as to dissolve it, and the liquor filtered from the charcoal, acidulated with a few drops of *pure* hydrochloric acid, then boiled with a piece of very bright copper wire immersed in it, the copper will soon become coated with a steel-like layer of metallic arsenic, which can be sublimed into a white powder (arsenious acid) and on this being dissolved in distilled water, the addition of a drop or two of liquid nitrate of silver produces a characteristic yellow precipitate: the sensibility of this test being equal to 150,000th, *i. e.* a grain diffused through two gallons of liquid would be rendered evident.

In making this communication I wish to be distinctly understood as having no intention to cast any reflection upon parties concerned in Smethurst's case, but simply to relate, for the benefit of others, the facts as they have occurred to me in actual practice.—*John Horsley, F.C.S.*

Laboratory, Cheltenham.

Oak Rot.—A correspondent (*J. D.*) wishes to know if any of our readers can inform him why it is that oak rots *green*. He has noticed it in considerable quantities in the oak plantations at Lynmouth, and also at Tunbridge Wells. Is it, he asks, a chemical action? or is it caused by the growth of fungi?

LABORATORY MEMORANDA.

Pure Benzole from Coal-naphtha.—The sulphite of phenyle and ammonium $C_{12}H_5.NH_4.2\,SO_2$, usually called sulphobenzolate of ammonium, yields a very large proportion of pure benzole when submitted to dry distillation. The hydrocarbon thus procured can hardly be distinguished from the benzole obtained by heating benzoic acid with lime. Its odour is etherial, almost fragrant; and its boiling point is constant at 80°·3. A chemist well acquainted with the ordinary benzole obtained from coal-naphtha, to whom I showed a specimen of the benzole thus prepared from the sulphobenzolate of ammonium, scarcely recognised it as the same substance, so pleasant was its odour.

To prepare the sulphobenzolate, the purified benzole of commerce is dissolved, with the aid of a gentle heat, in a slight excess of fuming sulphuric acid; if ordinary oil of vitriol be employed, a much larger quantity of the acid is required. The acid liquid, after having been heated in the water bath for some time, is allowed to cool, and then diluted with water. Commercial carbonate of ammonium, together with some ammonia water, is to be added till the solution is slightly alkaline. The whole is now evaporated to dryness on the water-bath, and the dry mass exhausted with boiling alcohol. The greater part of the sulphate of ammonium remains in the residue. The alcoholic solution of the sulphobenzolate of ammonium is to be transferred to a retort, and submitted to distillation. When all the alcohol has distilled over, the receiver is changed, and the heat raised. The benzole which collects in the receiver is accompanied by small quantities of solid products and by water. From these it may be separated by the addition of a strong potash-solution, and the removal of the supernatant oil by the pipette. The benzole is then rectified off caustic potash. The benzole thus produced is perfectly pure; and although the quantity obtained is not very large, yet the result of the process is exceedingly interesting to the chemist, since it removes all doubt concerning the identity of the benzole from coal-naphtha and similar sources with that obtained from benzoic acid.—*A. H. Church.*

MISCELLANEOUS.

The Bath-bun Poisoning Case.—A case of wholesale poisoning which has occurred within the last day or two at Clifton demands from us more than a passing record. A baker in that place, wishing to save his eggs and exaggerate his reputation, desired some yellow colouring matter to give a fictitious appearance of richness to his Bath-buns. Low eating-house keepers and cheap pastry-cooks in London have long been in the habit of using turmeric to give this appearance to their delicacies, but the Clifton baker was not sufficiently well up to the tricks of his trade as to be aware of the uses of this harmless drug. Casting about, therefore, for some substance which would answer his purpose, he by some means fixed his mind on chrome yellow—chromate of lead. For this he applied to a druggist in his neighbourhood. A druggist who was not a colourman as well would not be likely to have chrome yellow in his shop, and this would appear to be the case with the Clifton tradesman. Accordingly, he sold the baker what he thought would answer the purpose of a yellow colouring matter just as well; and that substance was ORPIMENT! This the baker carried home, mixed in his buns, and sold them to his unsuspicious customers. The consequences were soon apparent. The first victims were some school boys, one of whom, with a good appetite and much pocket money, devoured three of the poisonous viands. They were all made exceedingly ill, and some narrowly escaped with their lives, Such is a simple narrative of this shameful case, in which it is hard to say which was most to blame, the baker who designed to put chrome yellow into his pastry, or the druggist who sold him *orpiment* instead of the less active poison.

Moulding Fruits and Insects in Metal.—Small castings of iron, copper, or any other metal, may be made in moulds composed of plaster of Paris. Such moulds are easily made, and are very suitable for such articles. Fac-similes of birds, flowers, fruit, and insects may be cast in plaster of Paris as follows: Make a tight box of boards, with two or three wooden pins in it, and suspend in it, by a piece of strong linen cord, the objects of which casts are desired; then take five parts of plaster of Paris and one of brickdust, make them into a paste of the consistency of cream, and fill the box up carefully so as to cover the objects without distorting them. The box—with the articles in the interior of the plaster—is now suffered to dry very slowly, it is then placed in a slow fire, the heat of which is increased gradually until the box is consumed, and the plaster heated red-hot. It is now to be taken out of the fire, and the places where the wooden pins were inserted will form small holes, opening into the interior. The place which was occupied by the leaves, flowers, or insects will be found to contain only ashes, which may be blown through the above-named holes with a pair of bellows, leaving a space inside of the form of the object to be cast. A small quantity of mercury may now be poured in through the hole left by the burnt cord; and upon shaking the ashes will be collected, when they may be all poured out through the holes. The molten copper or brass is now poured in by a jet through the hole, which may be enlarged for the purpose, and the air will pass out by the small opening left by the cord. When the metal is cold, the mould of plaster is broken and the casting taken from its interior. Groups of fruit, flowers, lizards, and frogs have been cast by this process with an exact faithfulness to nature.

ANSWERS TO CORRESPONDENTS.

Mr. A. W. P. Smith is thanked for his good wishes.

R. B. C.—1. When absolutely pure there is no difference; but corn spirit, unless highly rectified, usually contains some *fusel oil*, to which the disagreeable effects of that spirit are generally referred. 2. To detect strychnine in mice or other small animals, dry the stomach and bowels, with the contents and liver, carefully, and then break them up and digest in chloroform. Afterwards take some of the chloroform, and evaporate on a watch-glass. When dry, place the glass on white paper, and add a few drops of strong sulphuric acid and a small fragment of bichromate of potash, whereupon a bluish violet colour is produced, which passes into a reddish yellow, and finally becomes brown.

S. S.—Oxygen is obtained by heating binoxide of manganese, and hydrogen is obtained when zinc, water and sulphuric acid are brought into contact. Our correspondent should consult some elementary work on Chemistry. The mixture of the gases is highly explosive.

THE CHEMICAL NEWS.

VOL. I. No. 5. — January 7, 1860.

PROPOSED TOXICOLOGICAL COMMISSION.

TOXICOLOGICAL science has of late years made great advances, and as far as inorganic poisons are concerned, it may almost be regarded as perfect. By a few experiments with trustworthy reagents, in the hands of a competent and conscientious chemist, the presence in the body of the smallest quantity of a mineral poison which can destroy life or even affect health, is easily and distinctly demonstrated beyond the possibility of a doubt. It is otherwise, however, with the organic poisons. Although some of these are easily recognised, there are many which we have at present no means of identifying, and we lately saw in the Poplar case the prisoner acquitted merely for the want of this positive identification. With regard to this particular case, we may remark, that a substance possessing all the physical characters of the matter which Dr. Letheby extracted from the stomach of the deceased, and capable of producing all the symptoms of which she complained, may be extracted from the shell of the cashew nuts which are commonly sold about the streets of London. It was introduced into medicine a few years ago as a vesicatory, under the name of *Cardole*, but it is little known to the medical profession. The acrid properties of the nutshell, however, are well known to children, who have blistered their mouths in extracting the kernels. Cardole, as usually prepared, though proving fatal to small animals, does not kill them so rapidly as the matter Dr. Letheby obtained from the stomach of the victim in the Poplar case; but it is likely that the means by which the doctor separated the poison may have procured it in a purer and more concentrated form. The subject certainly deserves further investigation, for here is a dangerous poison within the reach of any one who is acquainted with its properties, and wicked enough to make use of them.

We have made these observations partly with the view of introducing the following suggestion made in the last number of our valued contemporary, *Chambers's Journal*, a suggestion well deserving the attention of the public and the Government:—

"The recent poisoning cases, though no longer exciting public attention, are not forgotten among those by whom it is most to be desired they should be remembered — namely, men of science; for if it be true that the poisoner's skill has outrun the means of detection, so much the more need is there that chemistry should make a step in advance. This step, however, can only be made after a series of experiments of a highly refined character have been carried out; such as will enable the chemist in his laboratory to detect the subtlest cases. Results of this importance, involving a considerable amount of expense and labour, are beyond what we commonly expect from spontaneous individual research; and the subject is felt to be one which should be taken in hand by government. Let the proper authorities appoint a commission of two or three of our most competent chemists to work out a more perfect method of analysis than that at present in use, and pay them sufficiently, and there is good reason to believe that the result would be accomplished. Seeing that the public at large would be benefited by the result, there seems nothing unreasonable in looking to the public purse for payment; yet, taught by experience, no one is solicitous to bring the question forward, seeing how prone some feeble-minded members of parliament are to get up and oppose any scientific grant, especially one for the purpose of testing the effects of poison on animals, by the remark, at which the House is sure to laugh, that 'We don't want the public money wasted in poisoning dogs and cats.' It is only at times, and by a struggle, that the thousand pounds set down in the estimates for the encouragement of science does actually get voted; and yet the appropriation of that sum has hitherto rendered singular service to the mechanical, astronomical, and physical and chemical sciences. The poison-question is, however, of that importance that we trust it will not be allowed to slumber; and we make these remarks in the hope that it will be kept awake. We recommend it as a proper one for discussion to the CHEMICAL NEWS, a periodical which is to be supported by chemists in all parts of the realm."

Our toxicologists are real detectives, and the suggestion ought to be carried out merely as a matter of police. What is wanted is a general scheme for a complete examination of any suspected matters *for all known poisons*, and we are confident that we have toxicologists who could supply us with this, if they had any inducement to devote the time and labour which would be required for the preliminary researches. There can be no doubt that the best preventative of crime is certainty of detection; and nothing would do so much to stop poisoning as the knowledge that the poison is sure to be discovered.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Method of separating Phosphoric Acid from Bases, and principally from Alumina and Iron, by M. SCHULZE.

THE following method has been adopted by the author for the estimation of phosphoric acids in soils. We take about 50 grammes (770 grains) of the earth, and ignite it to destroy the organic matters, and then dissolve it in hydrochloric acid. The filtered liquor is nearly neutralised by dilute ammonia, care being taken not to reach the point when the precipitate of oxide of iron becomes permanent. The solution ought now to amount to about a pint and half. We now add 35 or 45 drops of perchloride of antimony, and set it aside for 12 or 24 hours. During this time there is deposited a yellowish-white flocculent precipitate which contains all the phosphoric acid, but is principally composed of antimonic acid, carrying with it some oxide of iron and alumina; it contains besides a quantity of ammonia, in proportion to that of the phosphoric acid. The precipitate, well washed with distilled water, is boiled with soda ley containing a certain amount of silicate. After boiling, the liquid is filtered; the oxide of antimony, changed into antimoniate of soda, remains on the filter with the alumina and oxide of iron. The filtered alkaline so-

lution, which contains the phosphoric acid with a little alumina and silica, is supersaturated with hydrochloric acid and ammonia, concentrated to evaporation, again treated with ammonia and then filtered. The precipitate of alumina and silica thus obtained, carries with it a small quantity of phosphoric acid. To remove this, the precipitate is redissolved in a drop or two of hydrochloric acid, the solution is evaporated to dryness, and the residue is warmed with a little acidulated water. After having filtered again to separate the silica, a small quantity of tartaric acid is added to the filtered liquor, which is then mixed with the preceding ammoniacal solution containing the greater part of the phosphoric acid. From these solutions the phosphoric acid is separated as phosphate of magnesia and ammonia in the usual manner.—*Annalen der Chemie und Pharmacie*, B. CIX.

TECHNICAL CHEMISTRY.

On the Ventilation of Sewers, by FREDERICK J. BURGE, *V.P. Metropolitan Association of Medical Officers.*

AT a time when all the engineering talent of the day has been endeavouring to solve the great question as to what is the best mode of conveying away the solid and liquid sewage of London, the chemical world has been, and must yet continue to be, actively engaged with the almost equally difficult problem, how to dispose of its gases generated *in transitu*.

That the passage of the sewage matter through the great culverts now being constructed upon improved principles, and with uniform falls, will be much more rapid than through the old and imperfect ones is to be fairly anticipated, but as the new system of house drainage, with its more complete trapping, will almost entirely prevent the escape of gases by the thousands of openings through which they have hitherto found vent, it will render it imperative that the arterial trunks shall be provided with an apparatus which, whilst it will offer no injurious impediment to the free passage of air from the sewers, will accomplish the chemical destruction of their deleterious gases.

In the early part of the year 1858 this subject engaged the attention of the Sanitary Committee of the Board of Works of the Fulham District, and Mr. Bean, their surveyor, and myself, their medical officer of health, were required to report thereon. The apparatus originally suggested by Mr. Bean consisted of a cast-iron box of about 18 inches cube, divided into two compartments and fitted with a cradle, which was destined to contain lime and charcoal broken into small pieces and mixed together, through which the gases would have to pass and be deodorised thereby. As it appeared to me, however, subsequently that several other deodorising agents might be made available, I proposed the substitution of a series of trays or a series of metal tubes placed side by side in a vertical position, with perforated bottoms for ensuring the more perfect and uniform contact of the sewage emanations with the disinfectant.

The apparatus is designed to be placed on the top of the common ventilating shaft in the centre of the roadway, and when in use presents the appearance of an ordinary grating.

The chemical agents which have principally engaged my attention at present have been—

1. Lime mixed with ordinary charcoal, as originally proposed by Mr. Bean, and exposed to the sewer emanations by means of his "cradle."

The whole of the sulphuretted hydrogen may thus be decomposed, and, I believe, some of the other gases decomposed or absorbed.

2. The oxides of iron, mixed with sawdust.

These agents have been most successfully used in the purification of coal-gas by the Imperial and other Gas Companies, which suggested to me the idea that, by the adaptation of a series of trays to the apparatus, so arranged as to ensure the perfect transmission of the entire sewer air through them, this mixture would form an admirable material for securing the object.

3. The oxides of iron, mixed with coarsely-powdered charcoal.

The operation of these would be somewhat similar to the preceding. There is, however, this drawback to the foregoing substances, that although the sulphuretted hydrogen and sulphide of ammonia would be totally annihilated, there are other gases arising from the decomposition of organic matter, which might possibly remain unaffected by them.

4. The manganate and permanganate of potass.

These constitute the active principles in Condy's disinfecting fluid, and form an admirable means for destroying impure gases. They, however, with others, have hitherto ranked only amongst the strictly *local* disinfectants, and from their non-diffusable nature could not be satisfactorily applied to the gases pervading the atmosphere of large sewers.

The mode by which I think they can be made available is by saturating very coarsely-powdered charcoal with a rather strong solution, and securing the passage of the sewer air through the material by means of the series of trays or metal tubes before alluded to.

The above chemical agents are none of them new, but are all well tried servants in sanitary science; nevertheless, though they have been used as disinfectants in the ordinary manner, none have as yet been applied to the decomposition of sewer gases in an apparatus so fraught with advantages as that suggested by Mr. Bean and myself. The manner in which they have been generally used has been by merely suspending flannels, &c. saturated with the various solutions, either in the sewers or ventilating shafts, necessarily allowing a very large proportion of the gases to escape, without contact with the disinfectant, a circumstance which it is believed will be avoided by the use of the proposed apparatus.

A very important advantage in it is that its action is entirely on the gaseous matters, that no extraneous substance is added to the contents of the sewers, and that it can with facility be applied to any of the existing shafts.

In order to test the efficacy of the principle, I had recourse to a series of laboratory experiments. An apparatus was fitted up for the purpose of generating sulphuretted hydrogen, to which a glass tube was adapted dipping into a receiver containing some very offensive cesspool matter in an active state of decomposition. To this receiver was connected another glass tube of large diameter placed horizontally, and containing small lumps of lime and charcoal through which the compound gases were made to pass. To this was attached another tube dipping into a saturated solution of acetate of lead. The evolution of sulphuretted hydrogen in this operation was continued for several consecutive hours, without the slightest discoloration of the lead solution. The results most fully demonstrated the practicability of entirely destroying the sulphuretted hydrogen, and fixing the ammonia. The only objection to the use of this mixture of lime and

charcoal is the occasional slacking of the lime from the humid air of the sewer and the water generated in the process and the subsequent condensation of the moistened powder.

In many later experiments the same kind of apparatus was used, substituting as the deodorising material oxide of iron mixed with coarse sawdust, in some instances the oxide mixed with small pieces of charcoal, and in other cases charcoal alone saturated with Condy's fluid. In nearly all the cases the results were highly satisfactory, the lead solution remaining perfectly clear. The experiments were varied in every possible way: sometimes the dipping tube, instead of being inserted into the solution of lead, was introduced into a vessel containing water only; and at others, opening into the room; but neither did the water nor the air of the apartment acquire any unpleasant smell.

In my next series of trials, I used the original wooden model, with trays and tubes closely fitted and cemented to prevent the escape of any of the gases, and subsequently applied one constructed of zinc to the crown of a large and very offensive cesspool.

During the early part of the year 1859, the Board of Works of the Fulham District ordered two of these ventilators to be cast in iron, and fitted to the shafts of one of the main sewers in Hammersmith. Upon these I have been successfully at work throughout the whole of the past summer.

Coincident with my experiments, Mr. Bean has caused an investigation to be made periodically by the person in charge of the sewer, with reference to its condition as indicated by the sense of smell, and for the purpose of ascertaining whether any change for the worse had occurred in consequence of the use of the apparatus. These examinations testify that the air of the sewers will not be in any way injuriously affected, and that whilst almost, if not quite, the whole of the nuisance arising from the old mode of ventilating them will by this means be annihilated, no impediment of consequence will be offered to the passage of the gases, neither can any ill consequence be expected to affect the workmen employed in cleansing or repairing them. An inquiry in the neighbourhood where the ventilators were used, satisfies me also that no injurious influence has been exerted on the house drains in consequence of my experiments.

In the present system of ventilation, it is found that in consequence of the iron gratings communicating directly with the sewer, a very large deposit of *débris* from the roadway takes place in that portion of it immediately underneath, particularly where the current is sluggish, and causes in many instances a great impediment to its proper flow. The catchpit which forms part of the deodoriser entirely obviates this evil, and is in itself a most important improvement.

If the apparatus now under notice fails to accomplish all that can be desired, I am quite certain that it will be instrumental in diminishing to a most sensible extent the offensiveness of the ventilating shafts; that its cost will not be excessive, and that the expense of maintaining it in action will be trifling compared with the advantages obtained. The charcoal may be washed and used almost *ad infinitum*. The oxide of iron may be revived by exposure to the air, and used for a very lengthened period, and even if Condy's patent solution were used, it may be purchased at a cost of about 1*s.* or 2*s.* per gallon.

Hammersmith, Dec. 1859.

[We insert the above communication as it contains some important points, but we believe the use of charcoal in similar trays has been made the subject of a patent.—Ed.]

PHARMACY, TOXICOLOGY, &c.

Leaves of the Castor Oil Plant.

The leaves of the castor oil plant, whether used internally or externally, are said to act as a lactagogue. At a meeting of the Medical Society of London, Dr. Routh exhibited three preparations of the leaves which had been made by Mr. Greenish, New Street, Dorset Square. These were a *tincture* and *liquor* (dose of each one drachm), and an extract (dose, five grains). The extract is made by evaporating a decoction to a proper consistence over a steam or water bath. The tincture is made with proof spirit, and is macerated the usual time; and the liquor may be prepared by percolation with cold water, a proper amount of spirit being added to preserve it, in the ordinary way.

The lactagogue properties of the leaves of the *Ricinus americanus* were known to the Spaniards of Peru and Chili. They applied them to the breasts to produce milk. Dr. McWilliam first drew the attention of the medical profession to the subject at the meeting of the British Association at Edinburgh, in 1850. The leaves of the plant are known at Boavista, in the Cape de Verd islands, as the *bofareira*, which is in reality the Ricinus communis of botanists, and occasionally the Jatropha Curcas, both belonging to the natural order of Euphorbiaceæ. Two kinds are known in these islands, the red and the white. The white only is used as a lactagogue. When the appearance of the milk is delayed, a decoction is made by boiling well a handful of the white *bofareira* in six or eight pints of spring water. The breasts are bathed with this decoction for fifteen or twenty minutes, and part of the leaves are applied as a poultice; the applications being repeated alternately for some hours, until the desired effect is produced.

Dr. Tyler Smith made some experiments with the plant used externally, and found it successful in three cases out of five.

Dr. Routh is the first who has used castor oil leaves internally in this country. He has given an infusion and also the extract in several cases with remarkable effect.

The leaves used by Mr. Greenish were obtained from Australia, from whence, if the medicine come into general use, any quantity may be obtained. The leaves grown in gardens here were not found so potent as those brought from Australia.

Adulterated Oil of Peppermint.

Adulterated oil of peppermint has been sold in the Philadelphia market within the last month or two. It is of a light yellow colour, but considerably darker than is usual with freshly distilled oil of mint, and presents the following characteristics: when evaporated from a piece of white unsized paper it leaves a yellow mark. Dropped into alcohol of 95 per cent. it does not disseminate itself, but falls to the bottom of the glass in broken globules, and collects in a distinct stratum.

Agitation produces dissolution, but the solution is turbid, with an amount of oil which should dissolve freely. It presents no reaction with chromic acid, but when dropped on a crystal of iodine, the iodine intumesces and fumes. No such reaction is produced by a pure oil of peppermint. The density of the oil is 0·870. A recent sample of Borton's oil gave a density of 0·90 These characteristics would point to turpentine as the probable adulteration. It has been suggested by a prac-

tised distiller of oil of peppermint that the adulteration was the essential oil of fireweed. This supposition was based on the peculiar strong smell left after most of the oil was volatilised from paper.

Recent oil of peppermint should volatilise completely from the paper without leaving a mark; when dropped into alcohol of 85 per cent. it should dissolve completely without agitation.—*American Journal of Pharmacy.*

ROYAL INSTITUTION OF GREAT BRITAIN.

A Course of Six Lectures[1] *(adapted to a Juvenile Auditory), consisting of Illustrations of the Various Forces of Matter, i. e. of such as are called the Physical or Inorganic Forces — including an Account of their Relations to each other; by* M. FARADAY, *D.C.L., F.R.S., Fullerian Professor of Chemistry, R. I., Foreign Associate of the Academy of Sciences, Paris, &c.*

LECTURE I. (Dec. 31, 1859.) — *The Force of Gravitation.*

IT grieves me much to think that I may have been a cause of disturbance in your Christmas arrangements, for nothing is more satisfactory to my mind than to perform that which I undertake; but such things are not always left in our own power, and we must submit to circumstances as they are appointed. I will to-day do the best I can; I will ask you to bear with me if I am unable to give more than a few words; and as a substitute I will endeavour to make the *illustrations* of the sense I try to express, as full as possible; and if we find by the end of this lecture, that we may be justified in continuing them, thinking that next week our power shall be greater,—why then, with submission to you, we will take such course as you may think fit,—either go on or discontinue them: and although I now feel much weakened by the pressure of illness (a mere cold) upon me, both in faculty of expression and clearness of thought, I shall here claim, as I always have done on these occasions, the right of addressing myself to the younger members of the audience,—and for this purpose, therefore, unfitted as it may seem for an elderly infirm man to do so, I will return to second childhood and become, as it were, young again amongst the young.

Let us now consider, for a little while, how wonderfully we stand upon this world. Here it is we are born, bred, and live, and yet we view these things with an almost entire absence of wonder to ourselves respecting the way in which all this happens. So small, indeed, is our wonder, that we are never taken by surprise; and I do think, that, to a young person of ten, fifteen, or twenty years of age, perhaps the first sight of a cataract or a mountain would occasion more surprise in him than he had ever felt concerning the means of his own existence; how he came here; how he lives; by what means he stands upright; and through what means he moves about from place to place. Hence, we come into this world, we live, and depart from it, without our thoughts being called specifically to consider how all this takes place; and were it not for the exertions of some few inquiring minds, who have looked *into* these things and ascertained the very beautiful laws and conditions by which we *do* live and stand upon the earth, we should hardly be aware that there was anything wonderful in it. These inquiries, which have occupied philosophers from the earliest days, when they first began to find out the laws by which we grow, and exist, and enjoy ourselves, up to the present time, have shown us that all this was effected in consequence of the existence of certain *forces*, or *abilities* to do things, or *powers*, that are so common that nothing can be commoner: for nothing is commoner than the wonderful powers by which we are enabled to stand upright—they are essential to our existence every moment.

Now, it is my purpose to-day to make you acquainted with some of these powers; not the vital ones, but some of the more elementary and, what we call, *physical* powers; and, in the outset, what can I do to bring to your minds a notion of neither more nor less than that which I mean by the word *power* or *force*? Suppose I were to take this sheet of paper, and were to place it upright on one edge, resting against a support before me, (as the roughest possible illustration I can give of something to be disturbed), and suppose I pull this piece of string which is attached to it. I pull the paper over. I have therefore brought into use a *power* of doing so—the *power* of my hand carried on through this string in a way which is very remarkable when we come to analyse it; and it is by means of these powers conjoined together (for there are several powers here employed) that I pull the paper over. Again, if I give it a push upon the other side I, bring into play a *power*, but a very different exertion of power from the former; or, if I take now this bit of shellac [a stick of shellac about 12 inches long and 1½ in diameter] and rub it with flannel, and hold it an inch or so in front of the upper part of this upright sheet, the paper is immediately moved towards the shellac, and by now drawing the latter away, the paper falls over without having been touched by anything. You see—in the first illustration I produced an effect than which nothing could be commoner—I pull it over now, not by means of that string or the pull of my hand, but by some action in this shellac. The shellac, therefore, has a *power* with which it acts upon the sheet of paper; and as an illustration of the exercise of another kind of power, I might use gunpowder with which to throw it over.

Now, I want you to endeavour to comprehend that when I am speaking of a *power* or *force*, I am speaking of that which I used just now to pull over this piece of paper. I will not embarrass you at present with the *name* of that power, but it is clear there was a *something* in the shellac which acted by attraction, and pulled the paper over; this, then, is one of those things which we call *power*, or *force*; and you will now be able to recognise it as such in whatever form I show it to you. We are not to suppose that there are so very many different powers; on the contrary, it is wonderful to think how few are the powers by which all the phenomena of nature are governed. There is an illustration of another kind of power in that lamp; *there* is a power of heat—a power of doing something, but not the same power as that which pulled the paper over: and so, by degrees, we find that there are certain other powers (not many) in the various bodies around us; and thus, beginning with the simplest experiments of pushing and pulling, I shall gradually proceed to distinguish these powers one from the other, and compare the way in which they combine together. This world upon which we stand, (and we have not much need to travel out of the world for illustrations of our subject; but the mind of man is not confined like the matter of his body, and thus he may and does travel outwards, for wherever his sight can pierce, there his observations can penetrate) is pretty nearly a round globe, having its surface disposed in a manner of which this terrestrial globe by my side is a rough model; so much is land and so much is water, and by looking at it here we see in a sort of map or picture how the world is formed upon its surface. Then, when we come to examine further, I refer you to this sectional diagram of the geological strata of the earth, in which there is a more elaborate view of what is under the surface of our globe. For, when we come to dig into or examine it (as man does for his own instruction and advantage, in a variety of ways), we see that it is made up of different kinds of matter, subject to a very few powers; and all disposed in this strange and wonderful way, which gives to man a history—and such a history—as to what there is in those veins, in those rocks, the ores, the water springs, the atmosphere around, and all varieties of material substances, held together by means of *forces* in one great mass, 8000 miles in diameter, that the mind is overwhelmed in contemplation of the wonderful history related by these strata (some of which are fine and thin like sheets of paper), — all formed in succession by the forces of which I have spoken.

Now, I shall try to help your attention to what I may say, by directing, to-day, our thoughts to one kind of power. You see what I mean by the term *matter*—any of these things that I can lay hold of with the hand, or in a bag (for I may take hold of the air by enclosing it in a bag)—they are all portions of matter with which we have to deal at present, generally or particularly, as I may require to illustrate my subject. Here is the sort of matter which we call *water* — it is *there* ice [pointing to block of ice upon the table], *there* water—[pointing to the water boiling in a flask]—*here* vapour—you see it issuing out from the top [of the flask]. Do not suppose that that ice and that water are two entirely different things, or that the steam rising in bubbles and ascending in vapour *there* is absolutely different from the fluid water — it may be different in some things, having reference to the *amounts* of power which it contains; but it is the same, nevertheless, as the great ocean of water around our globe, and I employ it here for the sake of illustration, because if we look into it we shall find that it supplies us with examples of all the powers to which I shall here refer. For instance, here is water—it is heavy; but let us examine it with regard to the *amount* of its heaviness, or its gravity. You see here I have a little glass vessel and scales [nearly equipoised scales, one of which contained a half-pint glass vessel], and the glass

[1] Reported verbatim by special permission.

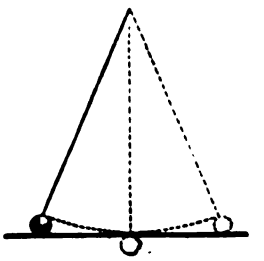
vessel is at present the lighter of the two; but if I now take some water and pour it in, you see that that side of the scales immediately goes down; that shows you (using common language, which I will not suppose for the present you have hitherto applied very strictly), that it is *heavy*, and if I put this additional weight into the opposite scale, I should not wonder if this vessel would hold water enough to weigh *it* down. [The Lecturer poured more water into the jar, which again went down.] Why do I hold the bottle *above* the vessel to pour the water into it? You will say, because experience has taught me that it is necessary. I do it for a better reason — because it is a law of nature that the water should fall towards the earth, and, therefore, the very means which I use to cause the water to enter the vessel are those which will carry the whole body of water down. That power is what we call *gravity*, and you see *there* [pointing to the scales] a good deal of water gravitating towards the earth. Now *here* [exhibiting a small piece of platinum] is another thing which gravitates towards the earth as much as the whole of that water. See what a little there is of it — *that* little thing is heavier than so much water [placing the metal in opposite scales to the water]. What a wonderful thing it is to see that it requires so much water as *that* [a half pint vessel full] to fall towards the earth, compared with the little mass of substance I have *here*; and again, if I take this metal [a bar of aluminium about eight times the bulk of the platinum] we find the water will balance that as well as it did the platinum; so that we get, even in the very outset, an example of what we want to understand by the words *forces* or *powers*.

I have spoken of water, and first of all of its property of falling downwards — you know very well how the oceans surround the globe — how they fall round the surface, giving roundness to it, clothing it like a garment; but, besides that, there are other properties of water. *Here*, for instance, is some quicklime, and if I add some water to it, you will find another power or property in the water. It is now very hot, it is steaming up, and if I had a bit of phosphorus here, or a match, I could perhaps light it. Now, that could not happen without a *force* in the water to produce the result; but that force is altogether very different from its power of falling to the earth. Then again here is another substance [some anhydrous sulphate of copper] which will illustrate another kind of power. [The Lecturer here poured some water over the white sulphate of copper, which immediately became blue, evolving considerable heat at the same time.] Here is the same water with a substance which heats nearly as much as the lime does, but see how differently. So great indeed is this heat in the case of lime, that it is sufficient sometimes (as you see here) to set wood on fire; and this is the reason of what we have sometimes heard, of barges laden with quicklime taking fire in the middle of the river, in consequence of this power of heat brought into play by a leakage of the water into the barge. You see how strangely different subjects for our consideration arise, when we come to think over these various matters — the power of heat evolved by acting upon lime with water, and the power which water has of uniting this salt of copper from white to blue.

I want you now to understand the nature of the most simple exertion of this power of matter called *weight* or *gravity*. Bodies are heavy—you saw that in the case of water when I placed it in the balance. Here I have what we call a *weight* [an iron half cwt.]—a thing called a weight, because in it the exercise of that power of pressing downwards is especially used for the purposes of weighing; and I have also one of these little inflated india-rubber bladders which are very beautiful although very common (most beautiful things are common), and I am going to put the weight upon it, to give you a sort of illustration of the downward pressure of the iron, and of the power which the air possesses of resisting that pressure — it may burst, but we must try to avoid that. [During the last few observations the Lecturer had succeeded in placing the half cwt. in a state of quiescence upon the inflated india-rubber ball, which consequently assumed a shape very much resembling a flat cheese with round edges.] There you see a bubble of air bearing half a hundred weight, and you must conceive for yourselves what a wonderful *power* there must be to pull this weight downwards, to sink it thus in the ball of air.

Let me now give you another illustration of this power. You know what a pendulum is. I have one here (*fig.* 1.) and if I set it swinging, it will continue to swing to and fro. Now, I wonder whether you can tell me why that body oscillates to and fro—that pendulum bob as it is sometimes called. Observe, if I hold this straight stick horizontally, as high as the position of the ball at the two ends of its journey, you see that the ball is in a higher position at the two extremities than it is when in the middle. Starting from one end of the stick, the ball falls towards the centre, and then rising again to the opposite end, it constantly tries to fall to the lowest point, swinging and vibrating most beautifully, and with wonderful properties in other respects—the time of its vibration and so on—but concerning which we will not now trouble ourselves.

Fig. 1.



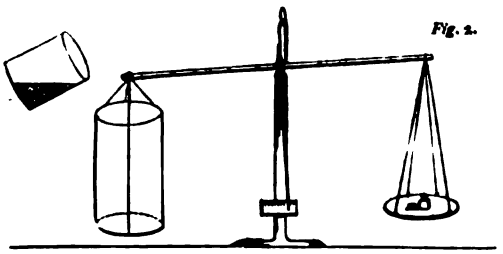
If a gold leaf, or piece of thread, or any other substance, were hung where this ball is, it would swing to and fro in the same manner, and in the same time too. Do not be startled at this statement; I repeat, in the same manner and in the same time, and you will see by and by how this is. Now, that power which caused the water to descend in the balance — which made the iron weight press upon and flatten the bubble of air—which caused the swinging to and fro of the pendulum, that power is entirely due to the attraction which there is between the falling body and the earth. Let us be slow and careful to comprehend this. It is not that the earth has any *particular* attraction towards bodies which fall to it, but, that *all* these bodies possess an attraction, every one towards the other. It is not that the earth has any special power which these balls themselves have not, for just as much power as the earth has to attract these two balls [dropping two ivory balls] just so much power have they in proportion to their bulks to draw themselves one to the other; and the only reason why they fall so quickly to the earth is owing to its greater size. Now, if I were to place these two balls near together, I should not be able, by the most delicate arrangement of apparatus, to make you, or myself, sensible that these balls did attract one another; and yet we know that such is the case because if, instead of taking a small ivory ball, we take a mountain, and put a ball like this near it, we find that, owing to the vast size of the mountain as compared with the billiard ball, the latter is drawn slightly towards it; showing clearly that an attraction *does* exist, just as it did between the shellac which I rubbed and the piece of paper which was overturned by it.

Now, it is not very easy to make these things quite clear at the outset, and I must take care that I do not leave anything unexplained as I proceed, and, therefore, I must make you clearly understand that all bodies are attracted to the earth, or, to use a more learned term, *gravitate*. You will not mind my using this word, for when I say that this penny piece *gravitates*, I mean nothing more nor less than that it falls towards the earth, and if not intercepted, it would go on falling, falling, until it arrived at what we call the *centre of gravity* of the earth, which I will explain to you by and by.

I want you, now, to understand that this property of gravitation is never lost, that every substance possesses it, that there is never any change in the quantity of it; and, first of all, I will take as illustration a piece of marble. Now this marble has weight—as you will see if I put it in these scales; it weighs the balance down, and if I take it off, the balance goes back again and resumes its equilibrium. Now I can decompose this marble and change it, in the same manner as I can change ice into water and water into steam. I can convert a part of it into *its own* steam easily, and show you that this steam from the marble has the property of remaining in the same place at common temperatures, which *water*-steam has not. If I add a little liquid to the marble and decompose it, I get that which you see—[the Lecturer here put several lumps of marble into a glass jar, and poured water and then acid over them; the carbonic acid immediately commenced to escape with considerable effervescence]—the appearance of boiling, which is only the separation of one part of the marble from another. Now this [marble] steam, and that [water] steam, and all other steams *gravitate* just like any other substance does; they all are attracted the one towards the other, and all fall towards the earth, and what I want you to see is that *this* steam gravitates. I have here (*fig* 2.) a large vessel placed upon a balance, and the moment I pour this steam into it you see that the steam gravitates. Just watch the index and see whether it tilts over or not. [The lecturer here poured the carbonic acid out of the glass in which it was being generated into the vessel suspended on the balance, when the gravitation of the carbonic acid was at once apparent]. Look how it is going down. How pretty that is! I poured nothing in but the invisible steam, or vapour, or gas which came from the marble, but you see that part of the marble, although it has taken the shape of air, still gravitates as it did before. Now,

will it weigh down that bit of paper? [Placing a piece of paper in the opposite scale.] Yes, more than that; it nearly weighs down

Fig. 2.



this bit of paper. [Placing another piece of paper in.] So that you now see that *other* forms of matter besides solids and liquids tend to fall to the earth; and, therefore, you will now accept from me the fact that *all* things gravitate, whatever may be their form or condition. Now *here* is another chemical test which is very rapid. [Some of the carbonic acid was poured from one vessel into another, and its presence in the latter shown by introducing into it a lighted taper, which was immediately extinguished.] You see from this also that it gravitates. All these experiments show you that, tried by the balance, tried by pouring it like water from one vessel to another, this steam, or vapour, or gas, is attracted to the earth just like other things.

Now there is another point that I want to draw your attention to. I have here a quantity of shot; each one of these falls separately, and each has its own gravitating power, as you perceive when I let them fall loosely on a sheet of paper. Now if I put them into a bottle I collect them together as one mass, and philosophers have discovered that there is a certain point in the middle of the whole collection of shots that may be considered as the *one point* in which all their gravitating power is centred, and that point they call the *centre of gravity*; it is not at all a bad name, and rather a short one—the centre of gravity. Now suppose I take a sheet of pasteboard, or any other thing easily dealt with, and suppose I run a bradawl through it at one corner A (*fig.* 3.) and Mr. Anderson holds that up in his hand before us, and I then take a piece of thread and an ivory ball, and hang that upon the awl, then the centre of gravity of both the pasteboard and the ball and string are as near as they can get to the centre of the earth; that is to say, the whole of the attracting power of the earth is, as it were, centred in a single point of the cardboard; and this point is exactly below the point of suspension. All I have to do, therefore, is to draw a line A B, corresponding with the string, and we shall find that the centre of gravity is somewhere in that line. But where? To find that out all we have to do is to take another place for the awl (*fig.* 4.), hang the plumb-line, and make the same experiment,

Fig. 3.

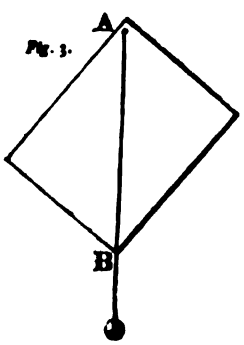


Fig. 4.

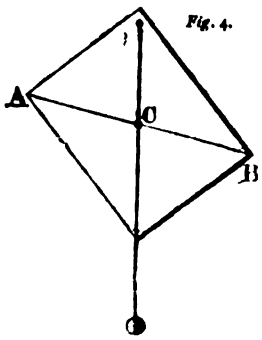


and there [at the point C] is the centre of gravity—there where the two lines which I have traced cross each other; and if I take that pasteboard, and make a hole with the bradawl through it at that point, you will see that it will be supported in any position in which it may be placed. Now, knowing that, what do I do when I try to stand upon one leg. Do you not see that I push myself over to the left side, and quietly take up the right leg, and thus bring some central point in my body over this left leg. What is that point which I throw over? You will know at once that it is the *centre of gravity*—that point in me in which the whole gravitating force of my body is centred, and which I thus bring in a line over my foot.

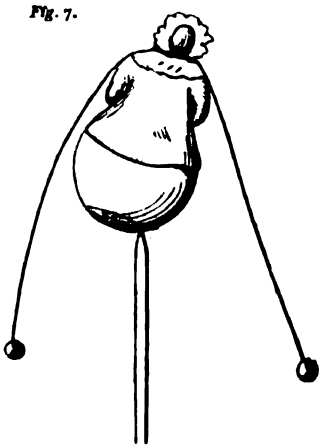
Now I have here a toy, which I happened to see the other day, and I think it will serve to illustrate our subject very well. That toy ought to lie something in this manner (*fig.* 5.). And

Fig. 5.

Fig. 6.

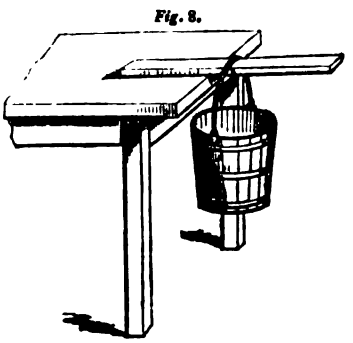
it would do so if it were uniform in substance; but you see it does not, it will get up again. And now philosophy comes to our aid; and I am perfectly sure, without looking inside the figure, that there is some arrangement there by which the centre of gravity is at the lowest point when the image is standing upright; and we may be certain when I am tilting it over (see *fig.* 6.) that I am lifting up the centre of gravity, and raising it from the earth. All this is effected by putting a piece of lead inside the lower part of the image, and making the base of large curvature, and there you have the whole secret. But what will happen if I try to make the figure stand upon a sharp point? You observe I must get that point *exactly* under the centre of gravity or it will fall over thus [endeavouring unsuccessfully to balance it]; and this you see is a difficult matter, I cannot make it stand steadily; but if I embarrass this poor old lady with a world of trouble, and hang this wire with bullets at each end about her neck, you see that it is very evident that owing to there being those two balls of lead hanging down on each side, in addition to the lead inside, I have lowered the centre of gravity, and now she will stand upon this point (*fig.* 7.); and, what is more she proves the truth of our philosophy by standing sideways.

Fig. 7.



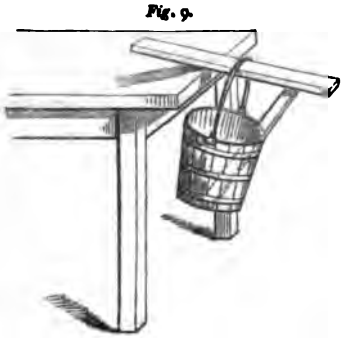
I remember an experiment which puzzled me very much when a boy. I read it in a conjuring book, and this was how the problem was put to us: "How," as the book said, "how to hang a pail of water, by means of a stick, upon the side of a table." Now I have here a table, a piece of stick, and a pail, (*fig.* 8.), and the proposition is how can that pail be hung to the edge of this table? It is to be done, and can you at all anticipate what arrangement I shall make to enable me to succeed? Why this. I take a stick, and put it in the pail between the bottom and the horizontal piece of wood, and thus give it a stiff handle, and there it is; and what is more, the more water I put into the pail the better it will hang. It is very true that before I quite succeeded I had the misfortune to push the bottoms of several pails

Fig. 8.



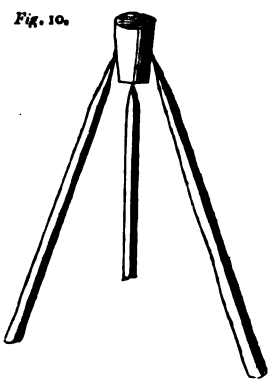
out; but here it is hanging firmly (*fig.* 9.), and you now see how you can hang up the pail in the way which the conjuring books require.

Fig. 9.



Again, if you are really so inclined (and I do hope all of you are), you will find a great deal of philosophy in this [holding up a cork and a pointed thin stick about a foot long]. Do not refer to your toy-books and say you have seen that before. Answer me rather, if I ask you, have you *understood* it before. It is an experiment which used to seem very wonderful to me when I was a boy; I used to take a piece of cork (and I remember, I thought at first that it was very important that it should be cut out in the shape of a man, but by degrees I got rid of that idea), and the problem was to balance it on the point of a stick. Why, you see I only have to stick two sharp-pointed sticks on each side, and give it wings, thus, and there you will find this beautiful condition fulfilled.

Fig. 10.



I want now to bring you to another point — all bodies, whether heavy or light, fall to the earth by this force which we call gravity. By observation moreover we see that bodies do not occupy the same time in falling: I think you will be able to see that this piece of paper and that ivory ball fall with different velocities to the table [dropping them]; and if again I take a feather and an ivory ball, and let them fall, you see they reach the table or earth at different times; that is to say, the ball falls faster than the feather. Now, that should not be so, for all bodies do fall equally fast to the earth. There are one or two beautiful points included in that statement. First of all it is manifest that an ounce, or a pound, or a ton, or a thousand tons, all fall equally fast, no one faster than another: here are two balls of lead, a very light one and a very heavy one, and you perceive they both fall to the earth in the same time. Now if I were to put into a little bag a number of these balls sufficient to make up a bulk equal to the large one, they would also fall in the same time; for if an avalanche falls, the rocks and mountains, snow and ice, together falling towards the earth, fall with the same velocity, whatever be their size.

I cannot take a better illustration of this than that of gold leaf, because it brings before us the reason of this apparent difference in the time of the fall. Here is a piece of gold leaf. Now if I take a lump of gold and this gold leaf, and let them fall through the air together, you see that the lump of gold — the sovereign, or coin — will fall much faster than the gold leaf. But why? They are both gold, whether sovereign or gold leaf. Why should they not fall to the earth with the same quickness? *They would do so*, but that the air around our globe interferes very much where we have the piece of gold so extended and enlarged as to offer much obstruction on falling through it. I will, however, show you that gold leaf *does* fall as fast when the resistance of the air is excluded—for if I take a piece of gold leaf and hang it in the centre of a bottle, so that the gold, and the bottle, and the air within shall all have an equal chance of falling, then the gold leaf will fall as fast as anything else. And if I suspend the bottle containing the gold leaf to a string, and set it oscillating like a pendulum, I may make it vibrate as hard as I please, and the gold leaf will not be disturbed, but will swing as steadily as a piece of iron would do; and I might even swing it round my head with any degree of force and it would remain undisturbed. Or, I can try another kind of experiment:—if I raise the gold leaf in this way [pulling the bottle up to the ceiling of the theatre by means of a cord and pulley, and then suddenly letting it fall to within a few inches of the lecture table], and allow it then to fall from the ceiling downwards (I will put something beneath to catch it supposing I should be *maladroit*), you will perceive that the gold leaf is not in the least disturbed. The resistance of the air having been avoided, the glass bottle and gold leaf all fall in exactly the same time.

Here is another illustration:—I have hung a piece of gold leaf in the upper part of this long glass vessel, and I have the means, by a little arrangement at the top, of letting the gold leaf loose. Before we let it loose we will remove the air by means of an air pump, and while that is being done, let me show you another experiment of the same kind. Take a penny piece, or a half crown, and a round piece of paper a trifle smaller in diameter than the coin, and try them side by side to see whether they fall at the same time [dropping them]. You see they do not —the penny piece goes down first. But, now place this paper flat on the top of the coin, so that it shall not meet with any resistance from the air, and upon *then* dropping them you see they *do* both fall in the same time [exhibiting the effect]. I dare say if I were to put this piece of gold leaf, instead of the paper, on the coin it would do as well. It is very difficult to lay the gold leaf so flat that the air shall not get under it and lift it up in falling, and I am rather doubtful as to the success of this, because the gold leaf is puckery; but I will risk the experiment. There they go together! [letting them fall], and you see at once that they both reach the table at the same moment.

We have now the air pumped out of the vessel, and you will perceive that the gold leaf will fall as quickly in this vacuum as the coin does in the air. I am now going to let it loose, and you must be quick to see how rapidly it falls. There! [letting the gold loose] there it is, falling as gold should fall.

I am sorry to see our time for parting is drawing so near. As I proceed I mean to put upon the board behind me certain words so as to recall to your minds what we have already examined; and I put the word Forces above all, and I will then add beneath the names of the special forces in the order in which we consider them; and although I fear that I have not sufficiently pointed out to you the more important circumstances connected with this force of Gravitation, especially the law which governs its attraction (for which, I think, I must take up a little time at our next meeting), still I will put that word on the board, and I hope you will now remember that we have in some degree considered the *force of gravitation*—that force which causes all bodies to attract each other when they are at sensible distances apart, and tends to draw them together.

(*The second Lecture, on* Gravitation *and* Cohesion, *will be given next Week.*)

NOTICES OF BOOKS, PATENTS, &c.

The Manufacture of Photogenic or Hydrocarbon Oils, from Coal and other Bituminous substances capable of supplying burning fluids, by Thomas Antisell, M.D., Professor of Chemistry in the Medical Department of Georgetown College, D.C., &c. &c. New York: D. Appleton & Co. 346 & 348 Broadway; London: 16 Little Britain. 1859.

It is seldom, indeed, that a work appears on any subject more opportunely than this. At the present moment, when the chief part of the globe is being ransacked to find bitumen, shales, and coals capable of yielding illuminating oils, when patents without number are being taken out, and schemes equally innumerable are being devised for obtaining and purifying them; at the present moment, we repeat, the work before us becomes invaluable. We feel this so strongly, that we believe there are many of our readers who will thank us for quoting the headings of the various chapters:—

I. Introduction — History of the Art.
II. On the Chemical Composition of Bituminous Coal, Bituminous Schist, Native Bitumens, Peat, and Organic Substances yielding Photogenic Oils.
III. On the General Principles involved in Destructive Distillation: resulting products obtained.
IV. On the products derived from the Distillation of Bituminous Coal.
V. On the products derived from the Distillation of Schists and Natural Bitumens.
VI. On the Distillation of Peat and Wood.

VII. On the various modes of applying heat in the process of distilling Photogenic Oils.

VIII. General Remarks on the Commercial Manufacture. — Synoptical *résumé* of patented improvements having reference to the Distillation of Oils from Coals, Bitumens, and Schists.

1. American Patents.
2. European Patents.

From the above table of contents, it is evident that the work before us contains information to be found in no other. The author is therefore justified in stating his treatise to be the first monograph published on the art of distilling oils from minerals containing bitumen.

The historical introduction is exceedingly interesting. It seems that the production of oils from coal was first observed during the first half of the eighteenth century.

"The discovery of the production of oils from coal appears to date as far back as the time of Boyle, when the experiments of Dr. Clayton were made upon the inflammable nature of the distillates of coal. These were first communicated to the public by the Royal Society of London many years after, in 1739. 'First,' says he, 'there came over a flegm, *then a black oil*, and then likewise a spirit (gas) arose, which I could in no wise condense.' This gas was such a matter of novelty and interest, that the appearance or nature of the oil was overlooked; and Clayton's experiments were wholly directed to the examination of the gas, and not of the fluid products."

Our author, a little further on, attributes the discovery of naphthaline to Reichenbach; this is an error, naphthaline was, unless we greatly err, first noticed some years before that date, by an English chemist named Garden. The latter extracted his substance from coal tar.

It is said that the celebrated Dr. Hope of Edinburgh, in concluding his lecture on products of destructive distillation, used to say: "Dr. Reichenbach, gentlemen, has also discovered in wood tar a number of substances, such as kreosote, piccamar, paraffine, cedriret, capnomore, and a host of others, but of no interest or importance whatsoever." If Dr. Hope were now alive, he would be one of the first to admit the great chemical principle, that the substances at one time the rarest and most difficult to prepare, are at another among the commonest and most useful.

The important observation (first made known by Reichenbach, but first practically worked out by James Young), that bituminous coal on distillation yields paraffine oil, has led to much litigation and controversy. On this subject our author has the following remarks: —

"An impression has taken hold of the American manufacturing public that the patent of James Young has no force, as it was not a new invention at the date of the patent; and from the unfavourable effect of that patent upon the actual manufacture of coal oils in this country, an ill-feeling has been produced against it. That the owners of this patent have not acted wisely by withholding sales and licences under it until very lately is to be regretted; but that it was a *bonâ fide* improvement in an art at the time when it was patented, and that therefore the patent was rightly issued in this country, there can be no shadow of doubt in the mind of anyone who carefully traces the steps of the discovery of the production of photogenic oils from different materials."

Further, with reference to Mr. Young's claims, and his successful production from coal of oils resembling those from bitumen, we have,

"This Mr. Young accomplished, and thereby is entitled to the merit of producing oils from coal by distillation, so as to establish a branch of industry; and this discovery of the value of coal is accorded to him by Reichenbach himself."

Apropos of James Young, there is an excellent account of Boghead coal and its products. He is, however, scarcely correct in the saying that

"When distilled, the Boghead coal yields several products, among which the absence of benzine is remarkable, it being present in but small quantities in the first distillation."

It is true that Boghead naphtha does not contain a very large quantity of benzole, but it is not by any means absent from the first distillation. In fact, the proportion is considerable, but it is mixed with so much of the homologues of olefiant gas and the alcohol radicals, that it does not show itself so plainly as in the distillate from ordinary coal tar.

Our author is always to be depended on as long as he confines himself to practical processes and accounts of inventions, but he is at sea at once when he attempts to grapple with chemical formulæ or abstract science. He quotes with equal confidence the results obtained twenty-five years ago and those of to-day. He is also easily led away by those apparently simple relations which some chemists delight in tracing between substances, which in reality are by no means sufficiently understood to allow of any theories being erected upon their resemblance to other bodies.

For example, he quotes the following passage, evidently regarding it as sound reasoning: —

"The solid bitumen of the Dead Sea and that of the Tar Lake of Trinidad, as well as the viscid varieties of that island, as also of many other parts, as at Bechelbronn, in France, &c. are apparently produced from the oxidation of petroleum, and their composition is exhibited in the following formulæ:—

Naphtha or petroleum, $C_{20}H_{16}$, or $C_{40}H_{32}$.
Asphalt or bitumen, $C_{40}H_{32}O$.

which manifests this derivation in a striking manner."—*Muspratt.*

Now the formula of naphtha or petroleum is not $C_{20}H_{16}$ or $C_{40}H_{32}$. It is in fact an excessively complicated mixture of hydrocarbons, some of which, by the way, are so difficult of oxidation, that their conversion into asphalt by any ordinary reaction is absurd and impossible. Moreover naphtha or petroleum consists of liquid hydrocarbons, which it would need unlimited faith to believe would yield asphalt by oxidation. Moreover, there is no guarantee whatever for $C_{40}H_{32}O$ being the formula for asphalt. It is true that its analysis may have yielded numbers agreeing with a formula, but to analyse a complex mixture, and giving the numbers which appear to agree with that analysis as being a formula, is as absurd as the proceeding of the chemist, who determining to humbly imitate Frankenstein, commenced his researches into the nature of animal bodies by making a combustion of a mouse, dried for the purpose at 212°, and carefully pulverised to ensure complete mixture.

Again, at p. 34, speaking of the products of the distillation of Rangoon tar, upon the examination of which MM. De la Rue and Müller have been engaged for some years, we have: —

"The liquid having the lowest specific gravity, and which comes out first by distillation, is an analogue of benzine, and has been termed *Sherwoodole*; it has analogous properties in dissolving grease, &c. It may be eliminated, as well as some benzole, which also forms, by nitric acid."

This unhappy paragraph is a mass of absurdities. In the first place, what are we to say of chemistry if its professors call Sherwoodole an analogue of benzole, because, like the latter, it dissolves grease! The truth is that the liquid absurdly called "Sherwoodole," is not in any way an analogue of benzole, but a mixture of benzole and its homologues with propyle, butyle, and other homologues of methyle. There are also present some substances with which we are not, as yet, sufficiently acquainted to speak more specifically. What *does* our author mean in the next sentence by saying, "it," (Sherwoodole) "may be eliminated as well as some benzole, which also forms, by nitric acid." Who ever "eliminated" benzole or "Sherwoodole," by nitric acid? Does he, by first speaking of "benzine," and then of "benzole," in almost the same paragraph, imagine them to be two different bodies? What does he mean by "which also forms"? indeed, does he mean anything?

It is really painful to see a useful book deformed in this manner.

Chapter iv. offers a great contrast to that we have just criticised. There is much information in it of a kind which must be invaluable to those who are engaged in distilling coals for photogenic purposes. The yield per ton of coke

tar, ammonial liquor and gas, are all clearly stated. The products of the distillation of the tar are also given in photogen, solar oil, ammonia, paraffine, &c.

Immediately after all this invaluable information come some scientific details connected with the constituents of coal tar, and, as usual, our author is at sea directly. Dr. Antisell is afflicted with original ideas on chemical orthography. He sometimes uses and sometimes avoids the *e* final, without any rule whatever. Thus we have in the same table picoline and parvolin, benzin and toluene. At pages 52 and 53 we repeatedly have the word paraffin, but at p. 56 it is paraffine. Quinoline (chinoline) our author writes quinoleine, pyridine he writes pyrrhedine, for pyrène, he substitutes pyrrhene. At pp. 70 and 71, he spells them correctly. According to Dr. Antisell, toluene and cumene are "highly fluorescent." This is erroneous.

We are told at p. 64 that carbolic acid "may be supposed to be formed from benzole, $C_{12}H_6$, by the addition of two equivalents of oxygen." This is equally successful with the author's theorising generally.

At p. 65 we are told that

"The heavy oil contains a singular organic product, first discovered by Dr. Hofmann, of London, and called by him 'kyanol,' or 'aniline,' which possesses the property of giving, with bleaching powder, nitric acid, and other reagents, a magnificent blue colour."

Until now, we always fancied that aniline was first formed from indigo by Fritzsche, and named by him from "anil," an Indian word for the indigo plant. We write from memory, and are unable at the present moment to refer to our library, but we also believe that Runge was the first to find aniline in coal tar, and that *he* called it "kyanol." Every one knows or ought to know, the superb researches of Hofmann on aniline, and that he has done far more for its history and that of organic alkaloids generally than any other chemist. He would be the first to repudiate the *discovery* of the base in question.

There is an absurd blunder also at p. 69. To explain it, it must be premised that at p. 27, Greville Williams's researches on the production of the alcohol radicals or isomeric bodies, from Boghead coal, are mentioned; the boiling points and specific gravities, &c. being given in a table. Now at p. 69 Williams's results are again quoted, but the products are stated to be obtained by distilling paraffine, and the investigation is attributed to Dr. Anderson. How the author fell into this error is not easy to see. Moreover, paraffine when pure distils almost entirely without decomposition.

Chapter v., although not absolutely free from error, is exceedingly valuable, because it contains a mass of information upon the yield of oils, &c. from a great number of shales, bitumens, and asphalts.

Chapter vi. is also useful, and generally very correct.

Chapter vii. is on "methods of applying heat." Here the author is at home with his work, and the information is of a most practical and important kind. We will quote the following as a sample of what the author can do:—

"Paraffin is not produced in tars of gasworks where a high cherry-red heat has been used; it is naphthaline which is the waxy solid found. At low-red heats it begins to be produced; while paraffine is evolved at temperatures beginning at 350°, and running up to a very low-red heat, not visible in the day-time. This, then, is the range of temperature within which the manufacture must be conducted. Pouillet has given the following table of temperatures, which will serve as an index to the proper understanding of this subject:—

Incipient redness	525°
Dull redness	700°
Cherry-red, commencing	800°
„ brighter	900°
„ full	1000°
Dark yellow-red	1100°
Bright ignition	1200°
White heat	1400°
Dazzling white heat	1600°

The range desirable for manufacturing gas lies between 800° and 1000°. That for the manufacture of oils terminates where that of gas manufacture begins; and perhaps the most efficient temperature is that which does not exceed 700°."

In this chapter there is a vast amount of information upon the form and materials of the retorts, &c. for distilling coals, shales, &c.

Chapter viii. is equally practical and useful. We have numerous processes for the preparation and purification of photogenic oils, we then have the American localities of manufacture, followed by a list of American and European patents.

To sum up: Dr. Antisell's work is indispensable to all who are engaged in manufacturing photogenic oils; but, as we said before, although his *practical* information is extensive and accurate, his *scientific* knowledge (at least as far as organic chemistry is concerned) is below par.

The Mineral Springs of Vichy; a Sketch of their Chemical and Physical Characters, &c. by A. B. Granville, *M.D., F.R.S., Author of the Spas of Germany, &c. &c.* Churchill: 1859.

As men condemned to good health and perpetual hard work we have often thought how pleasant it must be to be an invalid in easy circumstances: not to be very ill, not to be racked with gout, pinioned with rheumatism, or made unutterably miserable with dyspepsia; but only to have just so much no physician knows what, as to justify a man in thinking only of himself, as to call out the sympathies of good-natured friends, and before all, as to afford a reasonable excuse for an extended round of visits to those agreeable resorts of beauty, fashion, hypochondriacism, and rascality, the continental watering places. Under such circumstances, next June would certainly find us *en route* for Vichy, with Dr. Granville's book in our portmanteau. But as it is all we can concern ourselves about is the water the visitors drink and bathe in there.

Vichy is situated in the valley of the Allier, about 250 miles from Paris, and almost in the centre of France. It has been celebrated as a spa from the time of the Romans, and Dr. Granville conjectures that "*the* Cæsar may have *deposited* of the springs as he crossed the bridge over the Allier on his return from the siege of Gergovia." Since then, after passing through many vicissitudes, it has become the most popular mineral spa in France.

The geological features of the neighbourhood consist of granitic and sienitic rocks on which repose carboniferous limestone, travertine, and tufa. Through these the mineral waters surge in all directions, impregnating the entire mass of the lacustrine deposits, and forming calcareous concretions, and especially fibrous arragonite in the moveable alluvial soil.

Although, according to some authors, there are sixteen different springs in Vichy and its neighbourhood, some at a considerable distance from others, yet the chemical composition of the waters is almost identical, indicating a common origin for all. The temperature of the waters varies from 113° F. to 60° F., the difference being accounted for by the size of the streams and the distance they travel from the common source before they reach the surface.

The predominating ingredient in Vichy water is bicarbonate of soda, this salt forming 29·28 out of 38·75 grains of the solid elements which exist in 16 ounces of the water. The next is the free carbonic acid, which amounts to 15·21 cubic inches in the same quantity of water. Besides these, the water contains the sulphate, phosphate, arseniate, and borate of soda, chloride of sodium, carbonates of potash, magnesia, strontia, lime, iron, and manganese, silica, and according to some traces of iodine, bromine, lithia, and alumina. The quantity of arsenic, however, need not frighten any one from drinking Vichy water, inasmuch as the maximum quantity found has not exceeded one-thousandth part of a grain in a pint of the water.

Into the question "What are Vichy waters good for?" it is no business of ours to enter. All we can say is, that for gout and dyspepsia they would appear to be specifics. But let incautious drinkers beware. At times they are of laborious digestion and produce *un ballonnement du ventre*, which always indicates an approaching thunder-storm,—a rather inconvenient weather instrument, as Dr. Granville remarks.

"According to the estimate published by M. Bouquet, the total amount of mineral water brought to the surface by the different sources of Vichy and its neighbourhood is 62,050,000 gallons annually, which yield a produce of solid matter equal to 3,401,240 pounds in weight, of which quantity 2,244,750 pounds are carbonate of soda. This quantity of mineral water is accompanied by an escape of free carbonic acid equal to 2,279,790 pounds, representing 621,760 pounds of pure carbon.

Dr Parkins says they have never had outbreaks of epidemics at Vichy.

As an alkaline source Vichy has a superior rival in France itself, for at Val, in the Ardèche, 16 ounces of the water contain 58·24 grains of crystallised carbonate of soda.

The greater part of the water at Vichy is allowed to flow away into the Allier, but a part is evaporated down to obtain the Vichy salts, of which pastilles and some other preparations, and even confectionary, are made; the manufacture of a very fine bicarbonate of soda is also carried on. The water is concentrated by evaporation, and is then drawn off into thick earthen vessels, in which the carbonate of soda soon forms large transparent crystals. These are exposed to an atmosphere of carbonic acid, obtained from one of the natural sources, by which the crystals are converted into the bicarbonate.

Of life in Vichy Dr. Granville gives a very enticing account. The hotels are good and not dear. The visitors are free and sociable. Strauss comes with his band for a couple of months, and when he leaves in September, the visitors all depart too, and Vichy puts up its shutters until the following May.

Interesting as we have found Dr. Granville's book, we cannot help expressing a hope that when he writes again he may find time to correct his proofs. The misprints are very numerous; but with all these drawbacks the book is full of useful information for every one who is anxious to know anything of Vichy or its waters.

Improvements in dyeing cotton, wool, silk, flax, and other fibrous materials or fabrics. N. A. Grumbl, Paris, 1859.

The inventor obtains a fast black dye, and all the shades thereof, by the use of extract of logwood, bichromate of potash, and crystallised soda. The process is as follows: a bath is made by dissolving 1 pound of extract of logwood in 3½ pints of warm water. The cotton or other material is plunged into this bath, and is then wrung and dried by exposure to the atmosphere. After being thoroughly dried, it is plunged into a second bath prepared by dissolving ¾ lb. of bichromate of potash, and ¼ lb. of crystallised soda, in 3½ pints of water. After immersion in this bath, the cotton is wrung or pressed, and completed in the ordinary manner. The strength of the baths must be maintained by regular additions of the ingredients. When a fabric contains a mixture of cotton, silk, and wool, it is first plunged into a boiling bath of campeachy wood, and afterwards into a bath, at the same degree of heat, containing ¾ sulphate of copper, and ¾ bichromate of potash. Fabrics composed entirely of wool are treated in a similar manner.

Treating Straw for Paper; American Patent.

An improvement in treating straw for making a superior quality of paper has just been secured by letters patent to R. H. Collyer, and his process may be of some importance. The straw is first soaked or boiled in water to render it soft, then it is subjected to a cutting action and also to a grinding machine. This latter operation seems to be the improved feature. The straw is rubbed between grinding surfaces until every knot is crushed and made into impalpable pulp. In this finely subdivided state, the pulp is boiled in a strong caustic alkali, which dissolves all the silex (hard specks), and it is then reduced to a fine condition. The next process is that of bleaching, which is done by steeping it in solution of chloride of lime, in the usual way, the finishing steep being a weak *sour* of sulphuric acid, after which it is washed and beat up into the proper consistency, to be laid into webs in the machine.

CORRESPONDENCE.

Poisoning by Mistake.

To the Editor of the Chemical News.

Sir,—Every now and then the public are alarmed and druggists are scandalised by a case of *accidental poisoning*, or *poisoning by mistake*. A customer applying for tincture of rhubarb is served with tincture of opium, or a black draught bottle is filled up with liquor opii, or as in the case commented on in your leader last week, some one wanting chrome yellow is sold orpiment, or some other unaccountable blunder is made, which sometimes ends in the death of the customer and the ruin of the druggist. It may seem impertinent in me, but yet as having had a large establishment for many years without a case of the kind I have mentioned having happened to me, I feel inclined to give my fellow druggists a few words of advice on the arrangement of our bottles on the shelves. My remarks will not apply to the dispensing department, for it must be allowed that few accidents happen in that. It is in the retail that these dreadful blunders usually occur, and it seems to me that it must happen in consequence of poisonous remedies being kept in the same sized bottles, and in close proximity to other medicines of a similar appearance which are not poisonous. Now this is what I endeavour to avoid in the arrangement of my shelves. I keep tinct. opii in a smaller bottle, and on another shelf than tict. rhei. The trouble of filling once or twice oftener is quite compensated for by safety ensured. Another mistake made recently was selling sulphate of zinc for sulphate of magnesia. This perhaps occurred from a bad system of labelling, of which I have complained in other places. I always had the *principal* word written at as great a length as possible—zinci s. magnes s. for instance. Neither salt is likely to be mistaken for another salt of the same base; but if half or more than half the label was taken up by sulph. or sulphas, it is possible that that word only might be seen, and as the salts do somewhat resemble one another, the one might be taken for the other. But this could never happen except with criminal carelessness, if bottles were labelled as I suggest. I might write a good deal more to the same purpose, but I am sure I should only be writing thoughts which have at times occurred to every one of my fellow druggists who have thought on the subject.

Chemical Notices from foreign sources, by Dr. T. L. Phipson.

I. MINERAL CHEMISTRY.

Phenomena of Oxidation.—We have another long paper by M. Kuhlmann [1] on certain phenomena of oxidation by means of oxides of iron, manganese, and various salts. These phenomena of oxidation by the influence of a *third* substance, have been already explained by the writer of this article in his memoir "*Sur la Force Catalytique, &c.*" to which the *So-*

[1] *Comptes-Rendus*, Dec. 19, 1859.

ciété Hollandaise des Sciences, of Haarlem, awarded its gold medal in 1858. If M. Kuhlmann imagines he has brought out a new theory he is mistaken; many examples of oxidation by the influence of a third body were mentioned in the memoir just cited and reported to the combustion of hydrogen by oxygen under the influence of platinum.

Nor are the facts exposed by M. Kuhlman essentially new. Thus M. Chevreul was the first to notice that sulphate of lime gave oxygen to putrescent matter, and became sulphide of calcium. Liebig, in the introduction to his *Organic Chemistry* has mentioned the fact of iron pyrites found crystallised in cubes upon the decayed roots of trees which have remained for some time in water containing a small quantity of sulphate of iron.

On the production of rust upon a piece of iron, M. Kuhlmann says: "As soon as a spot of rust is formed upon the iron the metal is successively eaten away, because those parts which are immediately in contact with the rust are oxidised at the expense of its oxygen; afterwards the rust takes back from the air the oxygen it has lost," and so the oxidation continues. But we should like to be told how the *spot* of rust is formed in the first instance! M. Hervé-Mangon[2] explains the part played by peroxide of iron in nature[3] rather differently. According to the author this peroxide is not immediately reduced to protoxide by the organic matter in the soil, but combines with a certain acid (which he supposes to be the *crenic acid* of Berzelius) to form an *insoluble* salt of peroxide of iron. This salt when not exposed to the air passes to the state of protosalt, *i. e.* the acid it contains reduces the peroxide of iron to protoxide, and the new protoxide salt formed is *soluble* in water. If a drainage tube obstructed with an insoluble ochreous deposit, be filled with water and closed at both ends, the insoluble salt of peroxide of iron which forms the ochreous deposit disappears, is replaced by a soluble protoxide salt, which can easily be washed out of the tube. And when the protoxide salt in question is in contact with the atmosphere, the ochreous deposit is formed anew.

Decomposition of Sulphate of Zinc.—M. Persoz[4] starting from the formula: $ZnO,SO_3 + NaCl = NaO,SO_3 + ZnCl$, imagined that by heating a mixture of sulphate of zinc and chloride of sodium, he would be able to obtain chloride of zinc which, either anhydrous or in solution, is susceptible of many useful applications in the arts, &c. But he finds it far better to employ a mixture of one equivalent of sulphate of zinc, and one equivalent of *chloride of calcium*, because the volatility of the chloride of zinc and the infusibility of the sulphate of lime formed render the double decomposition more efficacious. The chloride formed is not altogether volatilised; ¼th, or thereabouts, remains in the retort with the sulphate of lime, but can be easily extracted by water, so that by this method the whole of the sulphate of zinc can be transformed into chloride, and thus may be utilised the large quantities of sulphate of zinc produced every year in galvanic piles.

Analysis of Boracite.—H. Rose found in 1858 that boracite contains chlorine as an essential element in its composition; the same fact had been already made known by M. Ludwig for Stassfurtite (a mineral from Stassfurth), and confirmed anew by M. Heintz, who established for the last named mineral the formula:

$$2(3MgO.\ 4BO_3) + MgCl,\ HO.$$

M. Potyka has more recently examined these two minerals. When both washed until the water which passes no longer precipitates with nitrate of silver, or with chloride of barium, and then dried at 100° (Centigrade), they give the following composition:—

	Boracite.	Stassfurtite.
Chlorine	8·15	8·02
Magnesium	2·75	2·71
Magnesia	25·24	26·15
Protoxide of iron	1·59	0·40
Boracic acid	62·91	60·75 (by difference)
Water	0·55	1·95
	101·19	99·98

The formula deduced from these numbers for boracite is:

$$2(3MgO.\ 4BO_3) + MgCl.$$

It only differs from Stassfurtite then by 1 equivalent of water.

II. ORGANIC CHEMISTRY.

Action of Baryta on Suberic Acid.—M. Alfred Riche has shown[6] that when suberic acid is heated with an excess of bayrta, a peculiar carburetted hydrogen distils. This substance boils at + 76° + (Centigrade), its analysis leads to the formula $C_{12}H_{14}$, corresponding to four volumes of vapour. Its formation may be thus explained:

$$C_{16}H_{12}O_6,\ 2HO + 4BaO = C_{12}H_{14} + 4(BaO.CO_2)$$

Suberic acid + baryta = hydrocarbon + carbonate of baryta.

This new hydrocarbon is insoluble in water, soluble in alcohol and ether. Its odour is rather aromatic, it takes fire easily and burns with a bright flame bordered with blue. The author has not yet decided where this new substance must be classed.

Butyric Acid.—Butyric acid is formed in a great number of circumstances,—in rancid butter, by the prolonged fermentation of starch, sugar, &c. M. Pelouze has found it in the excrements of man; it has been also recognised in sour soup and broth, and it is probably to butyric acid that is owing the nauseous taste of decomposed fruits, such as strawberries, &c. In this case the fruit has a taste of bad butter.

M. Isidore Pierre formerly demonstrated the presence of butyric acid in bad cider, which had occasioned various accidents to those who drank it. The same savant[7] has lately shown that this acid is likewise present in the fermented juice of frozen beetroot. This beetroot was on a heap of manure, which, together with a little flood of water that was close by likewise contained butyric acid. This water having been drunk by some horses occasioned illness. The butyric acid was found in these cases combined as a salt. M. Pierre's researches took place at Caen; he affirms, however, that MM. Verdiel and Risler have found found butyric acid in manure and in the soil of the Agronomical Institute of Versailles.

Essence of Cloves.—Professor Boettger[8] has made the following curious observations. When dry oxide of silver is damped with essence of cloves, the mixture takes fire spontaneously and the oxide is reduced to the metallic state. The same takes place with peroxide of silver obtained by electricity, and with oxide of gold. With peroxide of lead and chloride of lime the essence becomes heated and evolves smoke. It has no action upon permanganate of potash or on oxide of mercury. The hydrocarbon oils that this essence contains when separated from the eugenic acid it also contains, do not act upon the above substances in the same intense manner.

III. CHEMICAL ANALYSIS.

Determination of Nitrogen by Volume.—In organic analysis when nitrogen is determined by volume, any substance in the combustion tube capable of reducing carbonic acid to oxide of carbon becomes at once a source of error. It has been asked lately, whether the copper which in these determinations is placed in the fore part of the tube is not capable of reducing carbonic acid. M. Limpricht having announced that such was indeed the case, that carbonic oxide was pro-

duced at a dark red heat, thereby throwing a doubt upon the exactness of nitrogen determinations by this method, M. Perrot undertook some experiments[9], and showed that copper reduced by hydrogen, as employed by M. Limpricht, had no reductive action upon carbonic acid, but that if a very slight quantity of brass were present, or iron, the carbonic acid is reduced easily. The copper used in M. Perrot's experiments, was obtained by roasting copper turnings, and then reducing them by hydrogen.

M. Schrötter[10] has made the following experiments upon the same subject.

1. Small bands of pure copper, obtained by rolling out copper wire, do not decompose carbonic acid at a red heat.

2. Copper turnings roasted and then reduced by hydrogen do not decompose carbonic acid at a red heat, if the hydrogen has been thoroughly expelled by a current of cold air.

3. Copper, obtained by reducing copper oxide, reduces carbonic acid at a red heat.

M. Schrötter supposes, therefore, that in M. Limpricht's experiments hydrogen was present in the copper employed. M. Perrot is of opinion that M. Limpricht's copper contained a little iron or zinc. However that may be, the experiments alluded to show us how very particular we should be, in nitrogen determinations by volume, that the copper employed be chemically pure.

SCIENTIFIC NOTES AND QUERIES.

Specific Gravity as a Test of the value of Gold Alloys.—Sir,—Having lately turned my attention to estimating the amount of gold in gold chains, necklaces, &c. by means of their specific gravities, I have been stopped in the inquiry by a query, which probably some of the readers of the Chemical News can solve. It is as follows:—"Has an alloy of gold a specific gravity the mean of its constituents, and if not, how may it be obtained?" If I err not, silver, copper and zinc are all the alloys found in gold articles. Such being the case should the subject be a little more investigated, I have no doubt we shall be soon able to put buyers of jewellery in possession of a simple means of ascertaining the value of their purchases. This will certainly check in great measure the impositions which I believe are constantly going on. — *Physeos Zetetes.*

[The specific gravity of an alloy is in most cases *not* the mean of that of its constituents. The subject mentioned by our correspondent is, however, well worth investigation, as doubtless a table could be easily constructed by means of which the amount of gold in an alloy could be approximately ascertained. Ed.]

Peroxide of Manganese as a Deodorising Agent.—Sir,—In reference to Mr. Spencer's letter on the action of the oxides of iron, I have found the peroxide of manganese to be a most invaluable agent, not only in decolorising, but deodorising, water and other neutral liquids. If a more powerful deodorant or disinfectant be required its admixture with chloride of lime, in proportion of $\frac{1}{8}$ths manganese and $\frac{1}{4}$th lime, accomplishes the object much better than anything else I am acquainted with, as experiments with sulphuretted hydrogen and alkaline hydrosulphurets will prove, whilst its cheapness is at once a recommendation.—*John Horsley.*

Peroxide of Lead in Lucifer Matches.—Sir,—I shall be greatly obliged if any of your readers can inform me of a practical formula for the preparation of lucifer matches with peroxide of lead, which I see in your Chemical Notices is extensively employed in the fabrication, and also what is the advantage of its use.—*W. M.*

MISCELLANEOUS.

Sorgho Dye.—A. Winter, of Austria, has discovered a carmine-colouring matter in most parts of the Chinese sorgho, especially in the expressed stem, and has obtained a patent in Austria, Baden, and other states. The process is as follows:—The sorgho is pressed in the usual manner, and the empty cane piled up under cover in regular heaps, several feet high, and the fermentation which immediately sets in is so directed by more or less access of air as to prevent it from becoming putrid. After two weeks the whole mass is of a reddish-brown or red colour, when the fermentation is interrupted by drying. When dry, the mass is ground sufficiently fine for the extraction of the colouring matter. It is covered in the proper vessels with cold soft water, and allowed to stand for 12 hours; but little of the pigment dissolves during that time. It is then drained, and afterwards treated with a weak caustic soda or potash ley until this no longer extracts anything. This solution is carefully neutralised with sulphuric acid, thus precipitating the colouring matter in red flakes, which, after settling, is washed with water, collected on filters, and dried. This colour dissolves in alcohol, alkaline leys, dilute acids, &c. and is employed for the dyeing of silks and woollens with the common tin mordants. The colours produced from it are said to be unchanged by light or by washing with warm soapsuds.—*American Druggist's Circular.*

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On Various Methods for the Estimation of Copper, by FREDERICK FIELD.

[SECOND PART.]

IN resuming the brief notice upon the various methods of estimating copper, it may be remarked that Dr. Mohr (*Liebig's Annalen*, May 1855, and *Chemical Gazette*, July 1855), in a paper upon the volumetric determination of hydrocyanic acid and the cyanides of the alkaline metals, recommends a solution of a copper salt added to the liquid to be tested containing excess of ammonia. The cupreous compound is added until a permanent blue colour is produced. He explains the theory as follows:

$$2\,NH_4Cy + CuO.SO_3 + xNH_4O = CuCy.NH_4Cy + NH_4O.SO_3 + xNH_4O.$$

"There are, therefore," he says, "two atoms of cyanogen and one of copper in the compound. All the experiments prove the existence of the compound $CuCy + NH_4Cy$, and show that no intermediate forms are produced in the process." That Dr. Mohr is correct in asserting the existence of $CuCy + NH_4Cy$, there can be little doubt, although I believe he has not succeeded in separating it from its solution. Many experiments I made some years ago convince me that a solution of a copper salt is a very delicate test for cyanogen, and that the strength of all alkaline cyanides and solutions of hydrocyanic acid can be most readily determined, and with the greatest exactness by this means, but the concluding portion of the paragraph quoted above, in which is said, "that no intermediate forms are produced in the process," is open to discussion. When cyanide of potassium or hydrocyanic acid is added to a strong solution of an ammoniacal salt of copper, green crystals of great beauty are deposited, only soluble after some time in cold ammonia. This has often happened in an assay of rich copper ore, when the solution was not sufficiently dilute, and caused much trouble, as the crystals settle quickly and adhere slightly to the glass — this compound has been analysed by Dufau, who gives the composition

$$2\,NH_3.Cu_2Cy.CuCy.$$

(Cyanide cuproso-cupric bi-ammoniacal), and more recently by Hilkenkamp, whose analysis leads to following formula:—

$$2\,NH_3.\,2\,Cu_2Cy.\,CuCy.\,+\,2\,HO.$$

varying considerably from the results obtained by Dufau. After separating the crystals by filtration, the mother-liquid deposits brilliant violet crystalline scales of great lustre, which consists of $2NH_3 2Cu_2Cy.CuCy$ or the green compound minus two equivalents[1] of water (Hilkenkamp).

Besides these two compounds, I have met with others which I believe have not been noticed. The solution from which the green and violet crystals have separated, is of a pale blue colour, and deposits after some days hard golden coloured crystals of considerable size and beauty.

Also when hydrocyanic acid, or a soluble cyanide is added in slight excess to an ammoniacal solution of copper, so as to render it colourless, brilliant pearly crystals, some exceeding an inch in length, are deposited after the lapse of a few weeks. This compound contains much less copper than that described by Mohr. It may be further added that when cyanide of potassium is mixed in slight excess with ammoniacal copper containing a large quantity of sesquioxide of iron or other insoluble substance, in suspension, small white feathery tufts form on the surface of the precipitate, after a few hours. These crystals are very soluble in water, and bear every resemblance to cupro-cyanide of ammonium ($Cu_2Cy.NH_4Cy$). All the other compounds mentioned above are perfectly insoluble in cold water; thus, even omitting the white crystalline body deposited after the solution becomes colourless, and the tufty crystals just mentioned, at least three compounds, green, violet, and yellow, are formed.

Notwithstanding this, however, it is certain that *two* atoms of cyanogen are necessary to decolorise *one* of copper in ammonia; and whatever may be the formulæ of the intermediate products, they are resolved into a compound containing two of cyanogen and one of metal. Dr. Mohr mentions as a converse to the estimation of hydrocyanic acid by copper, the estimation of copper by hydrocyanic acid. That eminent chemist was probably unaware of Mr. Parkes's method published some years previously.

Appended is a table containing some results of experiments made upon pure copper, and that metal when in conjunction with some others. As this subject was treated in the last paper upon the subject, no further comment is necessary.

1000 grains of solution of cyanide of potassium exactly decolorised 10·00 copper.

						Divisions of burette in grs.
10·00	Copper			require		1000
10·00	"	+	10 grs. of	Iron	"	1000

10·00	"	+	" "	Silver	"	1320
10·00	"	+	" "	Zinc	"	1250

[1] As the separation of these two beautiful compounds is attended with some difficulty when they are both in solution in ammonia, the following method employed by Mr. John Abel and myself in some researches upon the cyanides, may be adopted with advantage. On adding a solution of cyanide of potassium to a moderately strong solution of an ammoniacal salt of copper the green compound is precipitated, perfectly free from the *violet*. On pouring off the mother-liquid into weak hydrochloric acid di-cyanide of copper is precipitated. This substance dissolved in weak warm ammonia, and filtered, gives the violet crystals free from the *green*. In attempting to obtain the former compound by gentle evaporation of the filtrate from the green crystals, a mixture of both salts nearly always occurs.—*F. Field.*

The metals which I was unable to procure in their uncombined condition were estimated from their compounds.

Precipitation of Metallic Copper by Iron or Zinc.—The fact of this process being so well known and so frequently described would seem to render further remarks unnecessary, but to insure good results certain minutiæ must be attended to, or very grave errors are likely to occur. The method generally described is as follows:—

The substance containing copper is dissolved in nitro-hydrochloric acid, and the whole of the nitric acid expelled by evaporation and subsequent ebullition with excess of hydrochloric acid. A clean piece of iron or some fragments of pure zinc are placed in the solution until the whole of the copper is precipitated. The finely divided metal is removed from the precipitant, washed, dried at 212° and weighed.

In the first place the copper solution should not contain a great excess of hydrochloric acid, or the precipitated copper will adhere in flakes so closely to the iron as to prevent its removal. As much acid, therefore, as possible, should be driven off by evaporation, before the introduction of the iron. After all the copper is precipitated, the plate of iron removed, and the greater portion of the ferruginous solution decanted off, the addition of hot water immediately renders the remaining liquid turbid, from the formation of basic salts of iron. A few drops of hydrochloric acid dissolve these salts, and the washing and decantation may be continued. When it is considered that nearly all the iron has been got rid of (which generally happens after the fifth or sixth washing, if the precipitated copper only amount to 20 or 30 grains), a small quantity of the liquid is poured in a tube and ferrycianide of potassium added. If a blue colour is produced, of course the washing must be continued. When the copper has been proved to be free from iron it is carefully dried in the same basin in which it was precipitated, and weighed.

By far the most delicate part of the process is the washing of the copper. If too much hydrochloric acid be added, especially when the water is near the boiling point, and when the iron exists in very small quantity, a large portion of the copper is dissolved. This is particularly the case when the metal is very finely divided, and then long addition even of very weak hydrochloric acid dissolves a large amount with formation of sub-chloride. On the other hand, if no acid be employed it is impossible to remove the basic salts of iron, and much of that metal remains with the copper.

The solubility of copper in weak hydrochloric acid when the metal is finely divided, is indeed extraordinary. A moderately strong solution of subchloride of copper in hydrochloric acid can be obtained by digesting a quantity of precipitated copper with water containing ten per cent. *hydrochloric* acid for a few hours, at a temperature of about 140° Fahrenheit. Strong boiling acid has not nearly so powerful a reaction upon the metal. Although I am aware that it is always recommended to employ boiling water for the washing in this assay, I have seen such great mistakes made, involving such serious consequences, that I never have employed it myself. If water at about the temperature of 100° or 120° Fahrenheit be used, containing from one to two per cent. of hydrochloric acid, all ferruginous salts are removed, and no copper is dissolved. The operation is doubtless longer, but the object is accomplished. Many objections which have been mentioned cannot be adduced in the employment of zinc instead of iron. No basic salts are thrown down from the zinc solution by hot water, and therefore the addition of hydrochloric acid is unnecessary, a long continued washing with water being sufficient.

However carefully performed, this estimation is never *perfectly* correct. I have never examined copper precipitated either by zinc or iron without finding traces of those metals. At the same time there is always a slight loss of copper in the primary solution of the metal, filtration, and especially precipitation, during the effervescence produced by the evolution of hydrogen. In a commercial point of view, the small amount of foreign metals in the precipitated copper compensates for that loss, and it has been proved by numerous estimations that when all points of the operation have been carefully attended to, the copper obtained is not far from the truth. Pure crystallised sulphate of copper, for instance, yields within a few hundredths of a grain the calculated amount of metal.

Pelouze's Process.—The well known method first proposed by Pelouze for the estimation of copper, which consists in precipitating its sulphide by sulphide of sodium in an ammoniacal solution, although disapproved of by some chemists, appear (as far as my own experiments have gone) to be very accurate, if the precautions mentioned by the author be adhered to. The suspended oxide of iron in the solution does not interfere in any way with the success of the process, although it renders a very gradual and cautious addition of the alkaline sulphide necessary, and of course a longer time is required for the execution of the assay. The great instability of the sulphide of sodium solution, and the necessity of keeping the copper liquid at a high temperature during the precipitation, renders the process more irksome than many others which have been proposed.

Treille's Process.—In the *Comptes-Rendus* for Feb. 1858, M. Treille has given a process for the estimation of copper by permanganate of potash. The oxide of copper is dissolved in ammonia, sulphite of soda added until the solution becomes colourless; excess of sulphurous acid expelled by hydrochloric acid and ebullition, and the copper estimated by a standard solution of permanganate of potash. M. Treille remarks that the copper salts are completely reduced to the state of sub-salts by the addition of alkaline sulphites, but only in the presence of ammonia. I have not found this observation to be correct, for although it is difficult to deoxidise protosalts *completely* by sulphurous acid, in very acid solutions, the gradual addition of carbonate of soda, until a slight excess is introduced, perfectly accomplishes the deoxidation, the orange oxide being precipitated, which dissolves in hydrochloric acid with a colourless solution. It may be mentioned here that the simplest and by far the most expeditious method of converting proto- into sub-salts of copper by means of alkaline sulphites, is to mix about equal quantities of sulphite and carbonate of soda, and to make of these salts a strong cold solution. This liquid poured into a protosalt of

copper instantly decomposes it, and even in the cold, much yellow oxide is precipitated. After a few minutes boiling the whole is converted into suboxide, which dissolves in hydrochloric acid or ammonia with no shade of colour.[2]

F. Mohr's process consists in forming a potassio-tartrate of copper, precipitating with grape sugar, and dissolving the suboxide, after thorough washing, in hydrochloric acid, with the addition of chloride of sodium, by which a double chloride of copper and sodium is formed. A solution of permanganate of potash indicates the amount of copper. This method is not so simple as that of Treille, the grape sugar being difficult to wash from the suboxide. The use of chloride of sodium, and indeed, the formation of a double salt of sodium and copper in this instance is doubtful.

Schwarz obtains the suboxide in a similar manner, and dissolves it in an acid solution of perchloride of iron. Protochloride of copper is formed by the conversion of a portion of the perchloride of iron into the protochloride, and the metal in the latter salt estimated by permanganate of potash. The copper can therefore be easily determined by the amount of iron-salt deoxidised.

(To be continued.)

TECHNICAL CHEMISTRY.

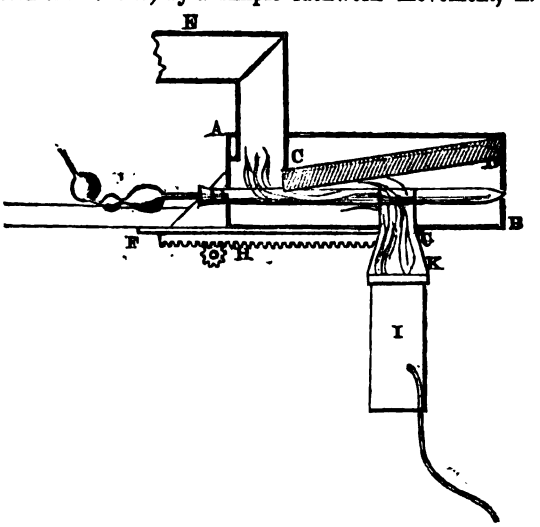
Description of a Simple Gas Combustion Furnace, by Alfred Sibson, *F.C.S., First Assistant in the Laboratory of the Royal Agricultural College, Cirencester.*

The accompanying sketch is intended to represent a new kind of combustion furnace which I devised some months ago, and have lately succeeded in perfecting. As it fully realises the expectations formed of it, and is now exclusively used (for the purposes presently to be mentioned) in our laboratory, the following description is supplied in the belief that the arrangement may possibly be of service in other laboratories.

This furnace is in no way intended to supersede, or even to compete with, Dr. Hofmann's gas-furnace, which in its latest form supplies all that can be desired for use in researches in organic chemistry. The present arrangement is suggested as a comparatively simple and inexpensive substitute for the above in cases where greater celerity and convenience are desired than can be obtained by the old method with charcoal.

The purpose for which this arrangement was devised, and for which it has proved most useful, is for making nitrogen determinations in guanos, superphosphates, or other artificial manures, for which comparatively short combustion tubes may generally be used. Some months constant use of the arrangement have proved that combustions of the above description can be made in it as completely as with charcoal, and with far greater celerity and convenience to the operator; it also allows of a more complete control over the operation than in the latter method.

The furnace is of simple construction, and can be made by any intelligent smith; it is not likely to get out of order, and consumes but little gas. Its principle will be understood if it is called a "Gas Reverberatory Furnace," a term perhaps not inappropriate, since a gas-burner corresponds to the fire of a reverberatory furnace, and its flame, after arching over, is drawn horizontally to a chimney on the same principle. The requisite extension of the fire is obtained by drawing this burner backwards from the chimney under which the front portion of the combustion tube is placed. The body of the furnace, A B, is simply a box of sheet iron of about 12 inches long, and 5 inches wide, and 4 deep, open at bottom and supported either by loops against a wall, or on legs. It is lined by a lump of fire-brick, C D, hollowed longitudinally, so as to leave an arched cavity through the furnace; the roof of this cavity is slightly lower at the chimney than at the further end; its dimensions are about 2 inches wide and 2 inches high at its highest part. The chimney C E, rises perpendicularly near the front end of the cavity above mentioned, and opens on a level with its roof. This chimney (also of sheet iron, about 2 inches diameter) must be connected with the flue of some furnace that is daily used, so as to insure a moderate draught. It should also be furnished with a damper to regulate the current of air passing through it. A separate iron plate, F G, having the burner attached to one end, is made to slide over the bottom of the frame, from end to end, by a simple rackwork movement, H.



The burner I, is a common wire gauze burner of iron about 3 inches square; it slides into a pyramidal funnel K, which leads the flame up into the cavity of the furnace. On a support attached to the further and upper end of this funnel one end of the combustion tube (or tubes, the furnace we use being constructed to make two combustions at once) rests, while the other end, having the nitrogen bulb attached, rests in a hole made to receive it in the front of the furnace, where there is an iron shelf provided to receive the bulb. The gauze burner is supplied with gas by a flexible tube, furnished with a stopcock, from any adjacent gaspipe.

In using the apparatus, the burner is drawn up close under the chimney, and the combustion tube, with its bulb attached, introduced by the hole above mentioned into the cavity of the frame, where it is supported on a narrow grooved slip of iron, one end of which [redacted] with the combustion tube at the front, and is [redacted] so as to prevent its being dragged by the motion of the burner.

[2] I am not aware if it has been observed by chemists that hydrated sulphite of copper (probably $Cu_2O.SO_2$, $CuO.SO_2$, xHO) is very soluble in carbonate of soda, forming a bright blue solution. When sulphate of copper, for instance, is precipitated by a strong solution of sulphite of soda, the precipitate is readily soluble in the alkaline carbonate.

A small flame is now to be lighted, so as to warm the tube gently, after which more flame is to be put on until the portion of tube exposed to it attains a good red heat; the fire is extended along the tube as the progress of the operation demands, by the means above mentioned, which allows of a very gradual extension of the heat, and the gas increased from time to time, so as to keep the tube well covered with flame. At the conclusion of the combustion, the draught may be increased and a large flame put on for a few minutes, which, wrapping round the tubes, heats them sufficiently to expel every trace of volatile matter. The gas is now turned off, and all subsequent operations performed as usual.

PHARMACY, TOXICOLOGY, &c.

On the Therapeutic Value of Medicinal Plants grown under certain conditions, by H. A. Tilden.

The American Pharmaceutical Association last year assigned to Mr. H. A. Tilden the question relating to the comparative therapeutic value of foreign and indigenous or cultivated plants. Such a question necessarily involved an extended series of observations and experiments lasting over two or more seasons, and he is only able this year to make a partial report. The part we extract from the *American Journal of Materia Medica* relates to the growth of hyoscyamus with different manures, showing their influence on the development of the active principle.

Pursuant to the general plan, he caused different sections of a large field of hyoscyamus, of the second year's growth, to be watered—one with a solution of nitrate of potassa, another with a solution of nitrate of soda, and another with a solution of guano—until the plants had reached maturity or the period of full bloom.

The plants watered exhibited marked difference in vigour of growth over other portions of the field, that portion upon which nitrate of potash had been applied being of a much darker green colour than that watered with nitrate of soda, and both much greener than that watered with solution of guano. The same difference in appearance was observable in a field of the same plant of the first year's growth.

At maturity the plants were collected and submitted to an uniform process of crushing, expression, and subsequent maceration of the pulp in alcohol. The expressed juice and alcoholic solution were evaporated to a pillular consistence.

A portion of each extract was dried, and treated by strong alcohol to dissolve the chlorophyll, alkaloid, and resinous principles evaporated, and treated with hot water to separate the resin and chlorophyll. The solution in hot water was boiled with oxide of lead, to separate the colouring matter, filtered, and the filtrate evaporated to dryness, giving a nearly white substance having marked alkaline reactions. Per centage in the extracts, as follows:—

	Ordinary cultivation.	Guano.	Nitrate of potassa.	Nitrate of soda.
Impure alkaline substance . . .	20·800	23·316	24·365	25·850
Colouring matter .	14·855	12·833	12·795	13·445

The alkaline principle, heated in a tube with *potassa*, disengaged ammonia largely, showing the presence of a large amount of *nitrogen*, and indicating the presence of a vegetable alkaloid.

The precise character of this impure alkaloid, to which the plant undoubtedly, to a great extent, owes its activity as a medicinal agent, we are now unable to state: reserving this for further examination.

The disengagement of strong ammonia indicates the presence of an alkaloid, probably *hyoscyamia*, as found by Brande.

The variation of this principle in the different extracts, as shown by the table above, enables us to draw the inference, fairly, that the different methods of treatment of the plant, or cultivation, produce a marked difference in its development; and we have no doubt, from the difference in the ammoniacal odour perceptible when each are tried with potash, that the pure hyoscyamia will be found to vary in similar proportion.

The *chlorophyll* and resin were separated by dissolving the *resin* in alcohol of the specific gravity of 90°, filtered, and the filtrate evaporated to dryness.

The residuum insoluble in alcohol was treated by cold water, to determine the *starch*; the soluble portion evaporated to a syrupy consistence, and the gum and albumen precipitated by alcohol.

The colouring matter contained in the aqueous part, together with the sugar, were not determined.

The result of the examination of this portion was as follows:—

	Ordinary cultivation.	Guano.	Nitrate of potash.	Nitrate of soda.
Soluble in alcohol .	47·244	49·229	45·269	44·829
Alkaline and colouring matter . .	35·433	36·453	32·162	39·325
Resin . . .	11·811	13·076	5·405	4·281
Chlorophyll . .	—	—	2·202	1·223
Starch . . .	2·482	2·561	1·992	1·999
Gum and albumen .	5·490	6·662	6·002	9·890

Another portion of each extract was dried and incinerated; the combustion was not carried far enough to produce entire destruction of the carbon. The ashes were then treated as follows:—

The carbonic acid gas was determined, by weighing, by hydrochloric acid, in the apparatus of Will; the solution was then placed in a porcelain dish, and evaporated to dryness, then dissolved in water, acidulated with a little hydrochloric acid, and filtered—the residuum upon the filter giving carbon and silica. From the filtered liquor all lime was precipitated by oxalate of ammonia, filtered, and the lime estimated in the state of sulphate of lime. The filtered liquor was evaporated to dryness, to expel the salt of ammonia previously added, and the residuum dissolved in water. To the solution was added ammonia, which precipitated the phosphate of magnesia, oxide of iron, and alumina. These were separated from each other by the usual known process. From the filtered solution free *phosphoric acid* was precipitated by sulphate of ammonico-magnesia.

Another portion of the ash was dissolved in water, acidulated with nitric acid, filtered, and divided into three portions. One portion was treated by nitrate of baryta, to determine the *sulphuric acid*, and by nitrate of silver, to determine the *chlorine*.

A second portion was treated by antimoniate of potash, to determine the soda; a *third*, by chloride of platina, to determine the *potassa*, and the nitric acid was estimated from another portion of the ash, by Pelouze's process.

The several extracts gave as follows:—

	Ordinary cultivation.	Guano.	Nitrate of potash.	Nitrate of soda.
Silica . . .	35·558	26·371	28·382	27·392
Phosphate of lime .	35·153	38·815	32·161	33·022
Carbonate of lime .	4·723	4·440	8·129	7·144
Phosphate magnesia .	6·932	10·764	5·231	5·707
Carbonate potash .	7·950	8·106	11·407	5·761
Sulphate potash .	1·895	2·860	3·012	1·769
Chloride potassium .	2·441	1·326	2·254	1·196
Nitrate potash . .	1·509	1·500	4·299	1·196
Oxide of iron . .	1·509	1·818	1·332	1·191
Alumina . . .	0·923	612	1·803	0·722
Nitrate of soda . .	—	—	—	0·391
Carbonate of soda .	—	1·800	—	10·084
Lost	1·407	1·588	1·990	1·425
Total . .	100·000	100·000	100·000	100·000
Ashes . . .	17·283	23·364	28·358	23·048
Total salts of potassa	13·795	13·792	20·972	9·822
Total salts of soda .	—	1·800	—	13·475
Total both .	13·795	15·592	20·972	23·297
Total phosphates .	42·085	49·592	37·392	38·379

It should be observed that the sections watered were sufficiently near as not to cause any variation in the character of the soil. It will be seen that potassa exists in the ordinary extract naturally, and is increased by special treatment nearly 50 per cent., while soda does not, and by treatment with soda the potassa is lessened from the natural proportion about 30 per cent., the total of soda nearly equals the total of potassa in the natural, and the nitrate of soda and nitrate of potassa taken together, exceeding the nitrate of potassa in the one treated by it, leaving the inference that when potassa exists in the soil and soda does not, that the latter should be used, so as to afford the largest amount of nitrates, and showing the disposition of the plant to take up both, unless it shall be shown by further investigations that the plant in which nitrate of potash exists naturally affords the largest amount of alkaloid, which is hardly probable.

This analysis explains the cause of the appearance of nitrate of potash, in crystals, upon the surface of the inspissated extracts of hyoscyamus.

It is not difficult to determine the different matters of which a plant is composed, but it is quite another field of investigation to determine the manner in which these substances are produced, and follow the complicated processes which constitute vegetation. The multiplicity of operations continually going on in vegetation at the same time, the variety of substances formed out of the same compound, the harmony, skill, and certainty which attends all the operations, are too wonderful to pass our observation, and too important not to challenge thorough investigation.

The researches and discoveries of agricultural chemistry fully establish the fact that plants require for their growth and perfect development certain inorganic constituents, which are different in different classes of plants. And the object of our inquiry is to ascertain what inorganic constituents are indispensable for the growth of the cultivated narcotics and perfect development of those principles, upon which their value as medicinal agents depends.

The utility of alkalies in the form of nitrates, or, indeed, in any form, cannot be doubted; nor can their utility in the formation of organic alkaloids in plants be considered a question.

Liebig says "the existence of vegetable alkalies in combination with organic acids gives great weight to the opinion that alkaline bases in general are connected with the development of plants;" and it remains to be determined by further experiment and analysis, which salt is most efficient in the development of the peculiar alkaloids upon which the medicinal activity of each narcotic appears to almost entirely depend, establish the true source of the active principles of other classes, and ascertain by what process the development of resinous and neutral principles likewise depends. — *American Journal of Materia Medica.*

ROYAL INSTITUTION OF GREAT BRITAIN.

A Course of Six Lectures[1] *(adapted to a Juvenile Auditory) consisting of Illustrations of the Various Forces of Matter, i.e. of such as are called the Physical or Inorganic Forces — including an Account of their Relations to each other; by* M. FARADAY, *D.C.L., F.R.S., Fullerian Professor of Chemistry, R.I., Foreign Associate of the Academy of Sciences, Paris, &c.*

LECTURE II. (Jan. 3, 1860.) — *Gravitation — Cohesion.*

Do me the favour to pay me as much attention as you did at our last meeting, and I shall not repent of that which I have proposed to undertake. It will be impossible for us to consider the Laws of Nature, and what they effect, unless we now and then give our sole attention, so as to obtain a clear idea upon the subject. Give me now that attention, and then I trust we shall not part without your knowing something about those Laws, and the manner in which they act. You recollect, upon the last occasion, I explained that all bodies attracted each other, and that this power we called *gravitation*. I told you that when we brought these two bodies [two equal sized ivory balls suspended by threads] near together they attracted each other, and that we might suppose that the whole power of this attraction was exerted between their respective centres of gravity; and, furthermore, you learned from me that if, instead of a small ball, I took a larger one, like *that* [changing one of the balls for a much larger one], there was much more of this attraction exerted; or, if I made this ball larger and larger, until, if it were possible, it became as large as the Earth itself — or, I might take the Earth itself, as the large ball — that *then* the attraction would become so powerful as to cause them to rush together in this manner [dropping the ivory ball]. You sit *there* upright, and I stand upright *here*, because we keep our centres of gravity properly balanced with respect to the earth; and I need not tell you that on the other side of this world the people are standing and moving about with their feet towards our feet, in a reversed position as compared with us, and all by means of this power of gravitation to the centre of the earth.

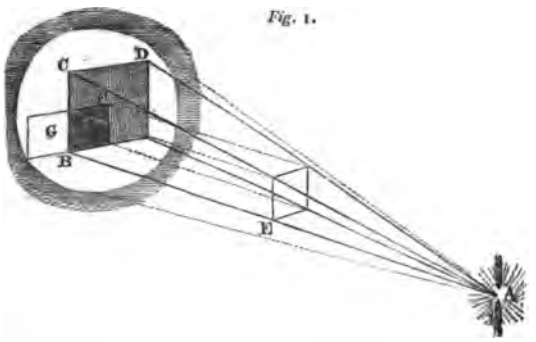
I must not, however, leave the subject of gravitation, without telling you something about its laws and regularity; and first, as regards its power with respect to the distance that bodies are apart. If I take one of these balls and place it within an inch of the other, they attract each other with a certain power. If I hold it at a greater distance off, they attract with less power, and if I hold it at a greater distance still, their attraction is still less Now this fact is of the greatest consequence; for, knowing this law, philosophers have discovered most wonderful things. You know that there is a planet, Uranus, revolving round the sun with us, but eighteen hundred millions of miles off; and because there is another planet as far off as three thousand millions of miles, this law of attraction, or gravitation, still holds good, and philosophers actually discovered this latter planet, Neptune, by reason of the effects of its attraction at this overwhelming distance. Now I want you clearly to understand what this law is. They say (and they are right) that two bodies attract each other *inversely as the square of the distance*, — a sad jumble of words until you understand them; but I think we shall soon comprehend what this law is, and what is the meaning of the "inverse square of the distance."

I have here (*fig.* 1.) a lamp A, shining most intensely upon this disc B, C, D, and this light acts as a sun by which I can get a shadow from this little screen E F (merely a square piece of card), which, as you know, when I place it close to the large screen, just shadows as much of it as is exactly equal to its own size; but now let me take this card E, which is equal to the other one in size, and place it midway between the lamp and the screen; now look at the size of the shadow D D, it is four times

[1] Reported verbatim by special permission.

the original size. Here, then, comes the "inverse square of the distance." This distance A E, is *one*, and that distance A B, is *two*, but that size E being *one*, this size B D of shadow is *four*

Fig. 1.

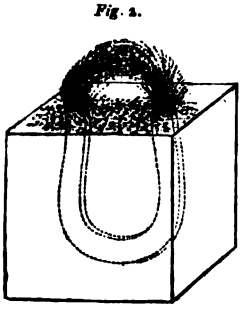


instead of *two*, which is the *square* of the distance; and, if I put the screen at one third of the distance from the lamp, the shadow on the large screen would be *nine* times the size. Again, if I hold this screen *here* at B F, a certain amount of light falls on it; and if I hold it nearer the lamp at E, *more* light shines upon it. And you see at once how much—exactly the quantity which I have shut off from the part of this screen B D, now in shadow; moreover, you see that if I put a single screen here at G, by the side of the shadow, it can only receive *one fourth* of the proportion of light which is obstructed. That, then, is what is meant by the *inverse* of the square of the distance. This screen E is the brightest because it is the nearest, and there is the whole secret of this curious expression *inversely as the square of the distance*. Now, if you cannot perfectly recollect this when you go home, get a candle and throw a shadow of something—your profile, if you like—on the wall, and then recede or advance, and you will find that your shadow is exactly in proportion to the *square* of the distance you are off the wall; and then if you consider how much light shines on you at one distance, and how much at another, you get the inverse accordingly. So it is as regards the attraction of these two balls, they attract according to the square of the distance, inversely. I want you to try and remember these words, and then you will be able to go into all the calculations of astronomers as to the planets and other bodies, and tell why they move so fast, and why they go *round* the sun without falling into it, and be prepared to enter upon many other interesting inquiries of the like nature.

Let us now leave this subject which I have written upon the board under the word Force—Gravitation—and go a step further. All bodies attract each other at sensible distances. I showed you the electric attraction on the last occasion (though I did not call it so); that attracts at a distance; and in order to make our progress a little more gradual, suppose I take a few iron particles [dropping some small fragments of iron on the table]. There, I have already told you that in all cases where bodies fall, it is the *particles* that are attracted. You may consider these then as separate particles magnified, so as to be evident to your sight; they are loose from each other—they all gravitate—they all fall to the earth—for the force of gravitation *never* fails. Now, I have here a centre of power which I will not name at present, and when these particles are placed upon it, see what an attraction they have for each other.

Here I have an arch of iron filings (*fig.* 2.) regularly built up like an iron bridge, because I have put them within a sphere of action which will cause them to attract each other. See!—I could let a mouse run through it, and yet if I try to do the same thing with them *here* [on the table] they do not attract each other at all. It is *that* [the magnet] which makes them hold together. Now just as these iron particles hold together in the form of an elliptical bridge, so hhdhe different particles of iron which constitute this nail hold together and make it one. And here is a bar of iron; why, is it only because the different parts of *this* iron are so wrought as to keep close together by the attraction *between* the particles, that it is held together in one mass. It is kept together, in fact, merely by the attraction of one particle to another, and that is the point I want now to illustrate. If I take a piece of flint and strike it with a hammer and break it thus [breaking off a piece of the flint], I have done nothing more than separate the particles which compose these two pieces so far apart, that their attraction is too weak to cause them to hold together, and it is only for that reason that there are now two pieces in the place of one. I will show you an experiment to prove that this attraction does still exist in those particles, for here is a piece of glass (for what was true of the flint and the bar of iron is true of the piece of glass, and is true of every other solid, they are all held together in the lump by the attraction between their parts), and I can show you the attraction between its separate particles, for if I take these portions of glass which I have reduced to very fine powder you see that I can actually build them up into a solid wall by pressure between two flat surfaces. The power which I thus have of building up this wall is due to the attraction of the particles, forming as it were the cement which holds them together; and so in this case, where I have taken no very great pains to bring the particles together, you see, perhaps a couple of ounces of finely pounded glass standing as an upright wall—is not this attraction most wonderful? *That* bar of iron one inch square has such power of attraction in its particles—giving to it such strength—that it will hold up twenty tons weight before the little set of particles in the small space equal to one division across which it can be pulled apart, will separate. In this manner suspension bridges and chains are held together by the attraction of their particles, and I am going to make an experiment which will show how strong is this attraction of the particles. [The Lecturer here placed his foot on a loop of wire fastened to a support above, and swung with his whole weight resting upon it for some moments.] You see while hanging here all my weight is supported by these little particles of the wire, just as in pantomimes they sometimes suspend gentlemen and damsels.

Fig. 2.



How can we make this attraction of the particles a little more simple? There are many things which if brought together properly will show this attraction. Here is a boy's experiment (and I like a boy's experiment).—Get a tobacco-pipe, fill it with lead, melt it, and then pour it out upon a stone, and thus get a clean piece of lead (this is a better plan than scraping it—scraping alters the condition of the surface of the lead). I have here some pieces of lead which I melted this morning for the sake of making them clean. Now these pieces of lead hang together by the attraction of their particles, and if I press these two separate pieces close together, so as to bring their particles within the sphere of attraction, you will see how soon they become one. I have merely to give them a good squeeze, and draw the upper piece slightly round at the same time, and here they are as one, and all the bending and twisting I can give them will not separate them again; I have joined the lead together, not with solder, but simply by means of the attraction of the particles.

This however is not the best way of bringing those particles together, we have many better plans than that—and I will show you one that will do very well for juvenile experiments. There is some alum crystallised very beautifully by nature (for all things are far more beautiful in their natural than their artificial form), and here I have some of the same alum broken into fine powder. In it I have destroyed that force of which I have placed the name on this board—Cohesion, or the attraction exerted between the particles of bodies to hold them together. Now I am going to show you that if we take this powdered alum and some hot water, and mix them together, I shall dissolve the alum—all the particles will be separated by the water far more completely than they are here in the powder; but then, being in the water, they will have the opportunity as it cools (for that is the condition which favours their coalescence) of uniting together again and forming one mass.

Now having brought the alum into solution, I will pour it into this glass basin, and you will, to-morrow, find that those particles of alum which I have put into the water, and so separated that they are no longer solid, will as the water cools, come together and cohere, and by to-morrow morning we shall have a great deal of the alum crystallised out, that is to say, come back to the solid form. [The Lecturer here poured a little of the hot solution of alum into the glass dish, and when the latter had thus been made warm, the remainder of the solution was added.] I am now doing that which I advise you to do if you use a glass vessel,

namely, warming it slowly and gradually; and in repeating this experiment do as I do; pour the liquid out gently, leaving all the dirt behind in the basin; and remember that the more carefully and quietly you make this experiment at home, the better the crystals. To-morrow you will see the particles of alum drawn together, and if I put two pieces of coke in some part of the solution (the coke ought first to be washed very clean, and dried), you will find to-morrow that we shall have a beautiful crystallisation over the coke, making it exactly resemble a natural mineral.

Now how curiously our ideas expand by watching these conditions of the attraction of cohesion — how many new phenomena it gives us beyond those of the attraction of gravitation. See how it gives us great strength. The things we deal with in building up the structures on the earth are of strength — we use iron, stone, and other things of great strength; and only think that all those structures you have about you — think of the Great Eastern if you please, which is of such size and power as to be almost more than man can manage — are the result of this power of cohesion and attraction.

I have here a body in which I believe you will see a change taking place in its condition of cohesion at the moment it is made. It is at first yellow, it then becomes a fine crimson red Just watch when I pour these two liquids together — both colourless as water. [The Lecturer here mixed together solutions of perchloride of mercury and iodide of potassium, when a yellow precipitate of biniodide of mercury fell down, which almost immediately became crimson red.] Now, there is a substance which is very beautiful, but see how it is changing colour. It was reddish-yellow at first, but it has now become red. I have previously prepared a little of this red substance, which you see formed in the liquid, and have put some of it upon paper. [Exhibiting several sheets of paper coated with scarlet biniodide of mercury.] There it is — the same substance spread upon paper, and there too is the same substance; and here is some more of it [exhibiting a piece of paper as large as the other sheets, but having only very little red colour on it, the greater part being yellow], a *little* more of it, you will say. Do not be mistaken; there is as much upon the surface of one of these pieces of paper as upon the other. What you see yellow is the same thing as the red body, only the attraction of cohesion is in a certain degree changed; for I will take this red body, and apply heat to it (you may perhaps see a little smoke arise, but that is of no consequence), and if you look at it it will first of all darken — but see, how it is becoming yellow. I have now made it all yellow, and what is more it will remain so; but if I take any hard substance, and rub the yellow part with it, it will immediately go back again to the red condition. [Exhibiting the experiment.] There it is. You see the red is not *put back*, but *brought back* by the change in the substance. Now [warming it over the spirit lamp] here it is becoming yellow again, and that is all because its attraction of cohesion is changed. And what will you say to me when I tell you that this piece of common charcoal is just the same thing, only differently coalesced, as the diamonds which you wear. (I have put a specimen outside of a piece of straw which was charred in a particular way — it is just like black lead). Now, this charred straw, this charcoal, and these diamonds, are all of them the same substance, changed but in their properties as respects the force of cohesion.

Here is a piece of glass [producing a piece of plate glass about two inches square], (I shall want this afterwards to look at and examine its internal condition)—and here is some of the same sort of glass differing only in its power of cohesion, because while yet melted it has been dropped into cold water [exhibiting a "Prince Rupert's drop" (*fig.* 3.)], and if I take one of these little tear-like pieces and break off ever so little from the point, the whole will at once burst and fall to pieces. I will now break off a piece of this. [The Lecturer nipped off a small piece from the end of one of the Rupert's drops, whereupon the whole immediately fell to pieces.] There! you see the solid glass has suddenly become powder, and more than that, it has knocked a hole in the glass vessel in which it was held. I can show the effect better in this bottle of water, and it is very likely the whole bottle will go. [A 6-oz. vial was filled with water, and a Rupert's drop placed in it with the point of the tail just projecting out; upon breaking the tip off, the drop burst, and the shock being transmitted through the water to the sides of the bottle, shattered the latter to pieces.]

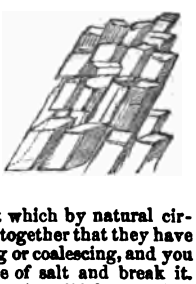
Here is another form of the same kind of experiment. I have here some more glass which has not been annealed, [showing some thick glass vessels (*fig.* 4.)], and if I take one of these glass vessels and drop a piece of pounded glass into it (or I will take some of these small pieces of rock crystal—they have the advantage of being harder than glass) and so make the least scratch upon the inside, the whole bottle will break to pieces,—it cannot hold together. [The Lecturer here dropped a small fragment of rock crystal into one of these glass vessels, when the bottom immediately came out and fell upon the plate.] There it goes through, just as it would through a sieve.

Fig. 3.

Fig. 4.

Now, I have shown you these things for the purpose of bringing your minds to see that bodies are not merely held together by this power of cohesion, but that they are held together in very curious ways. And suppose I take some things that are held together by this force, and examine them more minutely. I will first take a bit of glass, and if I give it a blow with a hammer I shall just break it to pieces. You saw how it was in the case of the flint when I broke the piece off; a piece of a similar kind would come off, just as you would expect; and if I were to break it up still more, it would be as you have seen, simply a collection of small particles of no definite shape or form. But supposing I take some other thing, this stone for instance (*fig.* 5.) [taking a piece of mica], and if I hammer this stone I may batter it a great deal before I can break it up. I may even bend it without breaking it; that is to say, I may bend it in *one particular direction* without breaking it much, although I feel in my hands that I am doing it some injury. But now, if I take it by the edges I find that it breaks up into leaf after leaf in a most extraordinary manner, Why should it break up like that? Not because all stones do. or all crystals; for there is some salt — (*fig.* 6.)—you know what

Fig. 5. *Fig.* 6. *Fig.* 7.

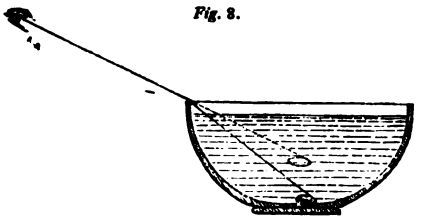


common salt is; here is a piece of this salt which by natural circumstances has had its particles so brought together that they have been allowed free opportunity of combining or coalescing, and you shall see what happens if I take this piece of salt and break it. It does not break as flint did, or as the mica did, but with a clean sharp angle and exact surfaces, beautiful and glittering as diamonds [breaking it by gentle blows with a hammer]; there is a square prism which I may break up into a square tube. You see these fragments are all square—one side may be longer than the other, but they will only split up so as to form square or oblong pieces with cubical sides. Now, I go a little further, and I find another stone (*fig.* 7.) [Iceland, or calc-spar], which I may break in a similar way, but *not* with the same result. Here is a piece which I have broken off, and you see there are plain surfaces perfectly regular with respect to each other, but it is not cubical — it is what we call a rhomboid. It still breaks in three directions most beautifully and regularly with polished surfaces, but with *sloping* sides, not like the salt. Why not? It is very manifest that this is owing to the attraction of the particles one for the other being less in the direction in which they give way than in other directions. I have on the table before me a number of little bits of calcareous spar, and I recommend each of you to take a piece home, and then you can take a knife and try to divide it in the direction of any of the surfaces already existing. You will be able to do it at once — but if you try to cut it *across* the crystals you cannot; by hammering, you may bruise and break it up — but you can only divide it into these beautiful little rhomboids.

Now I want you to understand a little more how this is — and for this purpose I am going to use the electric light again. You

see, we cannot look into the *middle* of a body like this piece of glass. We perceive the outside form, and the inside form, and we look *through* it, but we cannot well find out how these forms become so, and I want you therefore to take a lesson in the way in which we use a ray of light for the purpose of seeing what is in the interior of bodies. Light is a thing which is, so to say, attracted by every substance that gravitates (and we do not know any thing that does not). All matter affects light more or less by what we may consider as a kind of attraction, and I have arranged (*fig.* 8.)

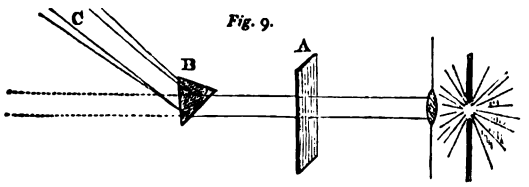
Fig. 8.



a very simple experiment upon the floor of the room for the purpose of illustrating this. I have put into that basin a few things which those who are in the body of the theatre will not be able to see, and I am going to make use of this power which matter possesses of attracting a ray of light. If Mr. Anderson pours some water gently and steadily into the basin, the water will attract the rays of light downwards, and the piece of silver and the sealing wax will appear to rise up into the sight of those who were before not high enough to see over the side of the basin to its bottom. [Mr. Anderson here poured water into the basin, and upon the Lecturer asking whether any body could see the silver and sealing wax he was answered by a general affirmative]. Now I suppose that everybody can see that they are not at all disturbed, whilst from the way they appear to have risen up, you would imagine the bottom of the basin and the articles in it were two inches thick, although they are only one of our small silver dishes and a piece of sealing-wax which I have put there. the light which now goes to you from that piece of silver was obstructed by the edge of the basin when there was no water there, and you were unable to see anything of it; but when we poured in water, the rays were attracted down by it over the edge of the basin and you were thus enabled to see the articles at the bottom.

I have shown you this experiment first, so that you might understand how glass attracts light, and might then see how other substances like rock salt and calcareous spar, mica and other stones would affect the light; and if Dr. Tyndall will be good enough to let us use his light again, we will first of all show you how it may be bent by a piece of glass (*fig.* 9.) [The electric

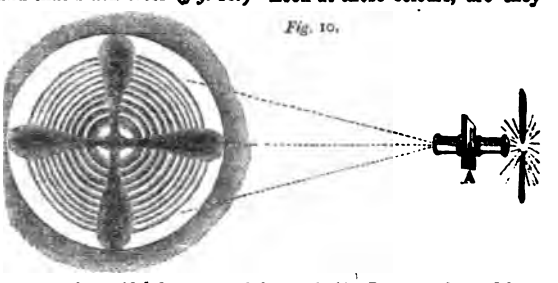
Fig. 9.



lamp was again lit, and the beam of parallel rays of light which it emitted was bent about and decomposed by means of the prism.] Now here you see, if I send the light through this piece of plain glass A, it goes straight through without being bent (unless the glass be held obliquely, and then the phenomenon becomes more complicated), but if I take this piece of glass B [a prism], you see it will show a very different effect. It no longer goes to that wall, but it is bent to this screen C, and how much more beautiful it is now [throwing the prismatic spectrum on the screen]. This ray of light is bent out of its course by the attraction of the glass upon it. And you see I can turn and twist the rays to and fro in different parts of the room just as I please. Now it goes there, now here. [The Lecturer projected the prismatic spectrum about the theatre.] Here I have the rays once more bent on to the screen, and you see how wonderfully and beautifully that piece of glass not only bends the light by virtue of its attraction, but actually splits it up into different colours. Now I want you to understand that this piece of glass [the prism] being perfectly uniform in its internal structure, tells us about the action of these other bodies which are not uniform—which do not merely *cohere*, but also have within them, in different parts, different *degrees of cohesion*, and thus attract and bend the light with varying powers. We will now let the light pass through one or two of these things which I just now showed you broke so curiously; and first of all I will take a piece of mica. Here you see is our ray of light—we have first to make it what we call *polarised*, but about that you need not trouble yourselves, it is only to make our illustration more clear. Here, then, we have our polarised ray of light, and I can so adjust it as to make the screen upon which it is shining either light or dark, although I have nothing in the course of this ray of light but what is perfectly transparent [turning the *analyser* round]. I will now make it so that it is quite dark, and we will in the first instance put a piece of common glass into the polarised ray so as to show you that it does not enable the light to get through. You see, the screen remains dark. The glass then, internally, has no effect upon the light. [The glass was removed, and a piece of mica introduced.] Now, there is the mica which we split up so curiously into leaf after leaf, and see how that enables the light to pass through to the screen, and how, as Dr. Tyndall turns it round in his hand, you have those different colours, pink, and purple, and green, coming and going most beautifully;—not that the mica is more transparent than the glass, but because of the different manner in which its particles are arranged by the force of cohesion.

Now we will see how calcareous spar acts upon this light,—that stone which split up into rhombs, and of which you are going to take a little piece home each of you. [The mica was removed, and a piece of calc spar introduced at A.] See how that turns the light round and round, and produces these rings and that black cross (*fig.* 10.) Look at those colours, are they

Fig. 10.



not most beautiful for you and for me? (for I enjoy these things as much as you do.) In what a wonderful manner they open out to us the internal arrangement of the particles of this calcareous spar by the force of cohesion.

And now I will show you another experiment. Here is that piece of glass which before had no action upon the light. You shall see what it will do when we apply pressure to it. Here, then, we have our ray of polarised light, and I will first of all show you that the glass has no effect upon it in its ordinary state,—when I place it in the course of the light, the screen still remains dark. Now Dr. Tyndall will press that bit of glass between three little points, one point against two, so as to bring a strain upon the parts, and you will see what a curious effect that has. [Upon the screen two white dots gradually appeared]. Ah! these points show the position of the strain—in these parts the force of cohesion is being exerted in a different degree to what it is in the other parts, and hence it allows the light to pass through. How beautiful that is—how it makes the light come through some parts and leaves it dark in others, and all because we weaken the force of cohesion between particle and particle. Whether you have this mechanical power of straining, or whether we take other means, we get the same result, and, indeed, I will show you by another experiment that if we heat the glass in one part it will alter its internal structure, and produce a similar effect. Here is a piece of common glass, and if I insert this in the path of the polarised ray, I believe it will do nothing. There is the common glass [introducing it]—no light passes through—the screen remains quite dark; but I am going to warm this glass in the lamp, and you know yourselves that when you pour warm water upon glass you put a strain upon it sufficient to break it sometimes—something like there was in the case of the Prince Rupert's drops. [The glass was warmed in the spirit lamp, and again placed across the ray of light.] Now you see how beautifully the light goes through those parts which are hot, making dark and light lines just as the crystal did, and all because of the alteration I have effected in its internal condition; for these dark and light parts are a proof of the presence of forces acting and dragging in different directions within the solid mass.

(*The third Lecture*, on Cohesion *and* Chemical Affinity, *will appear in our next.*)

PROCEEDINGS OF SOCIETIES.

PHARMACEUTICAL SOCIETY, *January* 4, 1860.

T. N. R. Morson, Esq. *President, in the Chair.*

The first paper was read *On the Preparation of Lard for Pharmaceutical purposes;* by Mr. T. H. Hills.

Mr. Hills believes that lard acquires its bad smell owing to the presence of a disagreeable odorous matter which is found between the lard and the membrane from which it is separated. When prepared in the usual way this odorous matter is dissolved and becomes diffused through the whole of the lard. In order to get rid of it and obtain the lard quite pure, Mr. Hills cuts up the flair, and before melting places it in a vessel with a perforated bottom (a sort of colander), and keeps a stream of water running through, squeezing and stirring the mass continually, so that every part of it may be exposed to the action of the water. By this means the odorous matter is washed away. Afterwards the lard is melted and strained from the membrane. Prepared in this way lard will keep without smell for 9 or 12 months. When *benzoated* lard is prepared, bruised benzoin is added previous to the melting, and the whole is maintained at a gentle heat for two hours and then strained.

Mr. Buckle had found it advisable to remove all the fat immediately around the kidneys and ureters (which always had a bad odour) before the lard was made. If this were done it might be prepared in the usual way without possessing any smell. He heated it to ebullition to get rid of the water.

Mr. Wright said that perfumers were the largest consumers of prepared lard, and they made it by cutting up the flair and boiling it with water, throwing in about 2 oz. of alum to the cwt. to coagulate albuminous and fibrinous matters, which they skimmed off.

Mr. Hills replied that the odorous secretion of which he had spoken was soluble in the heated lard, and could only be got rid of by washing with cold water, as he had described.

The next paper was *On Pilulæ*, by Mr. B. S. Proctor of Newcastle. The object in making pills was to form active ingredients into a mass with substances which should give plasticity, and at the same time promote the solubility, and obviate any liability to change. He believed it best to make only small quantities of a mass at a time, and for this reason recommended that the ingredients should be kept in powder ready to be made up with water, or what was most advisable, when the pills were required. If this plan were generally adopted he believed that the change would be acceptable to many. The objection that the ingredients of Plummer's pills were liable to separate he considered of no value. No objection was made to the keeping of powders (*e. g.* Dover's powder) on the same account. Making a solution of the ingredients, and then evaporating to a proper consistence, he thought had only a theoretical advantage, while the fact that pills made in this way soon fell out of shape was a positive disadvantage. Wholesale manufacturers who never saw pills after they had been in a patient's possession for a month, he did not consider were the best judges of what would form a good mass. A variety of pills might be made up with glycerine. Pil. rhei co. made up with it becomes tough and keeps well. Made up with treacle the mass is tough when new, but becomes hard. The best excipient perhaps was a mixture of 3 parts of treacle, 9 parts glycerine, and 4 parts water. The use of tragacanth, which had been condemned, was at times advisable. A small quantity of it removed the stickiness of the blue pill. Pills compounded of aloes and resins usually were of a bad shape. They were best made by dissolving the ingredients and evaporating with some substance which would give support to the mass. What he had found answer this purpose best was fine sawdust, which had passed through a sieve with about 40 meshes to the inch. If it were objected that sawdust was a vulgar substance, pure lignin or calisaya bark might be used, which would answer equally well. He had found that 60 grains of aloes could be made into a mass which kept its shape with 6 grains of sawdust and 6 minims of glycerine. Extract of gentian was often used to make aloes into a mass, under an impression that a bitter increased the action of the aloes. If this really were so he submitted that calisaya bark would answer the purpose just as well.

There was no discussion on this paper, for as soon as the reading was finished Mr. Waugh introduced a knife-cleaning machine to the notice of the meeting. It was made of two boards, one side of each having a cushion of felt over which was fixed a strip of buckskin leather—the leather surfaces being pressed together by means of screws passing through the ends of the boards. At the middle of the upper board was a small tin funnel through which emery powder could be passed to the cushions.

Mr. Hills then read a paper *On the Extract and Fluid Extract of Taraxacum.* He thought it best to collect the roots at the end of autumn or beginning of winter, after a little frosty weather. They should be washed, crushed, and then pressed, and the liquor should be boiled for a quarter of an hour. It ought then to be strained, and evaporated at a temperature from 80° to 100°. If the heat were increased to 212° the extract would become mouldy. If the fluid extract were required, 25 per cent. of spirit should be added to the juice, which should then be allowed to stand for the precipitate to separate, and then strained. The juice should never be heated, as it would not then keep well. With 20 per cent. of spirit he had found it keep well 12 months. To make extract from the dried root, it should be ground, and then percolated with 1 part of spirit and 4 of water, and the solution evaporated at a low temperature, as before.

Professor Bentley differed from Mr. Hills as to the time the root should be collected. The quality differed a good deal at different times of the year, and the goodness he considered to depend on the amount of bitter principle it contained. There was most of this in the spring. After a frost the root became sweet, which he believed was owing to the conversion of inuline into sugar; an opinion which was confirmed by analysis, which had shown that roots collected in autumn contain 2¼ ounces of inuline in the pound, while those collected in the spring had only a trace. He should like to see extracts prepared from roots collected in spring, autumn, and winter.

[The professor did not explain whether the bitter principle disappeared during the conversion of inuline into sugar, or whether its taste was merely covered by the sweetness of the sugar.]

Mr. Hanbury said that the Messrs. Smith of Edinburgh had shown that mannite was the saccharine principle developed in making the extract, and that none was formed if the process was well conducted. It was only when the roots were left long about, or when the process was prolonged, that mannite was developed. He thought some difficulty would be experienced in obtaining the roots in spring, as they were usually got when land was dug up in autumn.

A communication from Dr. Brett, *On Arsenical Fly Papers*, was then read. The Dr. had found two kinds of these papers; one which contained arsenic acid in combination with potash, and the other which contained only arsenious acid. In analysing the first the hydrochloric solution should be boiled with sulphurous acid before the arsenic was precipitated with sulphuretted hydrogen, or the arsenic would be under-estimated. The well-known *Papier Moure* belonged to the first class. He had analysed six specimens of arsenical fly papers, and had found one which contained as much as 15 per cent. of arsenious acid. He considered that they ought not to be sold, as their use was attended with danger.

Mr. Porrett said the use of polished visiting cards was dangerous to children. Cases of lead colic had occurred in children who had sucked these cards.

At the conclusion of the meeting Professor Redwood

rose to correct an error in the last number of the *Pharmaceutical Journal*. It was there stated that the sale of cocoa with dandelion did not require an excise license, but this had been found to be mistake, and he had thought it right to inform the members of it at once.

Mr. Buckle said he had made and sold *essence* of cocoa without a license, and he did not believe that one was required for essence of coffee.

A Member suggested that all difficulty about the sale of dandelion coffee might be removed if the dandelion were sold by itself, with a label directing the purchaser to mix it with an equal quantity of coffee when it was used. The meeting then adjourned.

Chemical Society.—We are requested to give notice that the next meeting of the Chemical Society will take place on Thursday the 19th inst., when several papers on Metallurgical Chemistry will be read.

NOTICES OF BOOKS, PATENTS, &c.

The Retrospect of Medicine: being a half-yearly Journal containing a retrospective view of every discovery and practical improvement in the Medical Sciences. Edited by W. Braithwaite, *Lecturer on Obstetric Medicine at the Leeds School of Medicine.* Simpkin, Marshall & Co. 1860.

The fortieth half-yearly volume of this valuable compilation is already before us. It contains a clear and well selected abstract of most of the papers of interest which appeared in the British Medical Journals from July to December of last year; and the promptitude with which the volume has been issued is highly creditable to both editor and publisher. As a matter of course, the work is intended for medical men, and contains but little of special interest to the mere chemist and druggist. But as we are not of the number who believe that the less a druggist knows of medicines beyond their prices and appearances, the better it is for himself, the public, and the medical profession, we shall always feel it our duty when giving an account of new medicines not only to notice their natural history, chemistry, and preparation, but also their effects and therapeutical uses. Not, however, with any view to assist chemists and druggists in prescribing, but because we believe it to be as important that they should know the properties of the articles they sell and compound, as that a man who deals in gunpowder should be aware of its explosiveness.

During the past half year, but few novelties have been introduced into our Materia Medica. A new diuretic has been found in the *Erodium Cicutarium*, or Stork's-bill, which grows abundantly on the sand-hills around our coast. It is administered in the form of an infusion made by steeping an ounce of the dried plant (every part of it) in 3 pints of water, and evaporating at a gentle heat to 2 pints. The dose of this infusion for an adult is 4 or 5 ounces 3 times a day.

Another novelty is *Saccharated Lime*, which is recommended as the best antacid which can be had. The way it is prepared is as follows:—

"Slake 8 ounces of quick lime; rub up with it 5 ounces of white sugar; add one pint of water; stir for some time until the hard stiff masses, which the sugar and lime are liable to run into, are as much as possible dissolved; then filter. The product should be perfectly clear and only of a slightly yellowish tint. A solution made in this way will contain 18 grains of lime in every ounce by weight."

It is given in doses of 20 or 30, or even 60 or more minims in a glass of water, two or three times a day, and is said by Dr. Cleland to be very useful in some forms of dyspepsia, in gout, and in checking diarrhœa.

Ozonised oils, that is, oils which have been saturated with oxygen and then exposed for some time to the direct rays of the sun, are said to have a remarkable tendency to reduce the frequency of the pulse. Cocoa-nut oil, sunflower oil, and cod-liver oil have been ozonised and used with great advantage in consumption, and no doubt ozonised cod-liver oil will soon be in demand. Ozonised oil of turpentine has also been used as a styptic.

A new and potent drug, the *Veratrum Viride*, has been extensively used in America. American practitioners tell us that by exhibiting in repeated doses a concentrated tincture of the *veratrum viride* they can reduce the pulse and keep it reduced with a certainty and to a degree which can be effected by no other drug. The *veratrum viride* is an American plant, but Dr. Simpson thinks that the same indications may be fulfilled with the *veratrum album*. We are not informed how the tincture was made, but the dose appears to have been from 3 to 10 drops.

Mercurial cigarettes have been recommended for several diseases. They are made by dissolving 15 grains of nitrate of mercury in 15 minims of strong nitric acid diluted with 6 drachms of water, and soaking in the solution strips of thick white blotting paper. These are rolled into cigarettes before they are quite dry, and gummed along the edge.

A disinfecting powder, made by mixing 100 parts of plaster of Paris with from 1 to 5 parts of coal tar, has been used with advantage in the Paris hospitals. The powder, it will be seen, resembles Mr. Dougall's. It may be made into a sort of ointment by rubbing it up with olive oil, and then may be applied directly to a wound.

Sulphuric ether is again coming into use as an anæsthetic. The only objections made to its employment were the time and the quantity of ether it required to get a patient fully under the influence. It seems odd that a few pence and a few minutes should be so much considered when life is at stake; but people are at times strangely economical, and operating surgeons are a peculiarly irritable race. While, however, chloroform remains in use, it is very important that our readers should know every means by which its purity can be ascertained, so we quote the following:

"Chloroform may contain chloride of elaidine, alcohol, various chlorides, amylic and methylic combinations, and aldehyde. By adding caustic potash to chloroform containing chloride of elaidine the compound is transformed into chloride of acetyle, the fœtor of which is immediately noticed. In order to ascertain the presence of all the other compounds which may be mixed with the chloroform, especially alcoholic compounds, pound a small quantity of bichromate of potash in a little chloroform, and add to this mixture a few drops of sulphuric acid. If the chloroform is pure, a reddish brown precipitate of chromic acid is formed; if not pure the acid is reduced, whilst the precipitate and sometimes the liquid itself assumes a green colour, dependent on the presence of the sesquioxide of chromium."

Mr. Braithwaite's *Retrospect* is too well known to medical men to need any recommendation from us. All we can say is that the present volume maintains the reputation of those which have preceded it.

Improvements in making extracts from Liquorice Root. A. W. Williamson, 1859.

Professor Williamson's object is to obtain a larger quantity of extract than is obtained by merely boiling the liquorice root in the usual way. With this idea he first exhausts the air dried root with water in any convenient manner, and afterwards boils it in fresh water containing about three fifths per cent. of dry potash in proportion to the original weight of dry root. After sufficient boiling, he separates this decoction, and evaporates it with the solution previously obtained to dryness, or any convenient consistence. Part of the potash may be replaced by an equivalent quantity of caustic soda.

We do not know that the amount of alkali an extract so made will contain is of much importance, but we are certain that it can be of no advantage; in some cases in which liquorice extract is used in pharmacy it may be decidedly objectionable. In any case, however, it seems — what shall we say — extraordinary, to see an accomplished chemist taking out a patent for boiling liquorice root in a little alkaline water.

CORRESPONDENCE.

Druggists' Labels.

To the Editor of the Chemical News.

Sir, — The letter of your correspondent * * * * contained a very good suggestion to which I would add another, which is that the labels in the retail department should all be in plain English. Why should any one coming for two or three pennyworth of tincture of rhubarb be served from a bottle mysteriously labelled Tinct. Rhei? or why should not black draught have black draught plainly written on it, instead of Haust Sennæ, or something else even less explicit? The absurdity of these things must be evident to all, and one wonders that the foolish and pedantic practice should be so general. If there be any excuse for those I have instanced above, there surely can be none for keeping arrowroot in a drawer labelled Fec. Marantæ, or Epsom salts in vessels marked Magnes. Sulph. These are quite as ridiculous as the case of a country druggist who sold gunpowder, and kept it in a drawer labelled Pulv. Pro. Gun!!

I know that it is not possible for every one to have a distinct dispensing department, but whenever it can be done I am sure it would be well to follow the practice I have suggested. Retail customers will be better satisfied when they can read the labels on the drawers and bottles from which they are served, and the mystery of a prescription can be just as well kept up if it be necessary.—I am, &c.

Cui Bono.

Mechanical Antidote for Arsenic.

To the Editor of the Chemical News.

Sir, — The present excitement about poisons reminds me to communicate a method of treating a case of poisoning by arsenic when it has been taken in a solid form, which I have seen used several times with perfect success, but never remember to have seen in print.

It consists in first evacuating the contents of the stomach and then well washing it out, and afterwards administering a good quantity of prepared chalk and castor oil, mixed together to the consistence of thick cream. The patient is made to eat a pound or more of this compound, which invests every particle of arsenic left adhering to the mucous membrane of the stomach, and carries it harmless through the remainder of the alimentary canal. Only one of several cases I have seen treated in this way proved fatal. One case in which a man had made a very determined attempt at suicide by swallowing arsenic and powdered nux vomica together, recovered after the treatment: the nux vomica symptoms, which were well marked, being combated with large doses of extractum conii.

The remedy is of Scottish origin, I believe, and was introduced at the London Hospital by Mr. Macmeikan, formerly apothecary to that institution.

I may add that the mixture of chalk and castor oil, flavoured with assafœtida and powdered gentian, and eaten with a teaspoon, has been found good *moral* treatment for an intended suicide, who has been supplied by a ready-witted druggist with cream of tartar or some other harmless substance in the place of a poison.—I am, &c.

W. T. Fewtrell.

Chemical Notices from Foreign Sources, by Dr. T. L. Phipson.

I. MINERAL CHEMISTRY.

Nitride of Selenium.—Professor Wöhler has lately addressed to the *Société Chimique* of Paris [1] the following note upon nitride of selenium:—"Having made one of my pupils, M. Espenschied, endeavour to obtain nitride of selenium, a compound hitherto unknown, we have succeeded perfectly in forming this compound. White volatile chloride of selenium is prepared (which probably is not $SeCl_2$ but $SeCl_4$); it is submitted, in a tube, to cold produced by a mixture of ice and common salt, after which a great excess of ammonia gas, perfectly dry, is passed over it. In this manner a brown matter is obtained, which appears to be a mixture of chloride of ammonium and nitride of selenium. At the ordinary temperature of the atmosphere the reaction is so vehement that only pure selenium, containing no nitrogen, is produced. By treating the brown matter with water the nitride of selenium is obtained, when it may be dried at a low temperature.

"Nitride of selenium is an amorphous powder of a fine red colour. It is a dangerous body to manipulate; when it is heated, rubbed, or struck with the hammer, it produces a violent explosion, and evolves into the air red fumes of selenium.

"M. Espenchied is at present occupied with the analysis of this new substance; at the same time he is endeavouring to produce, under the same conditions, *nitride of sulphur*."

Molybdate of Ammonia.—Since molybdate of ammonia has been employed in laboratories to detect the presence of phosphoric acid, many processes have been proposed for preparing molybdic acid. This acid is obtained generally by roasting the native sulphide of molybdenum in clay basins. M. Brunner [2] recommends a new method of performing this operation. The mineral is pulverised and mixed with an equal volume of quartzose sand; the mixture is then roasted in a platinum capsule until the mass has acquired a yellow lemon colour. After cooling the molybdic acid is extracted by exhausting the product with ammonia.

Transformation of Sulphate of Lead into Acetate.—This important industrial problem has lately been solved in a very satisfactory manner by M. Kraft.[3] Sulphate of lead is formed daily as a residue of the manufactory of of acetate of alumina for the dyers. To render this substance valuable, M. Kraft transforms it anew into acetate of lead, which can again react upon alum, and form acetate of alumina. First of all it is necessary to purify the sulphate of lead residue of the manufactories, by washing it with water containing sulphuric acid, or to destroy the organic matter it often contains, by calcining it in thin layers, and in contact with the air. This first operation terminated, 100 parts of the sulphate are taken, and boiled with 84 parts of *acetate of baryta* dissolved in as little water as possible. The reaction takes place rapidly, and can be effected easily, but at the expense of time, without the application of heat. The precipitate of sulphate of baryta formed is allowed to deposit itself, and the clear solution of acetate of lead is drawn off. The double decomposition takes place quite as well if the sulphate of lead be suspended in a bag, which is plunged into the solution of acetate of baryta. A slight excess of sulphate of lead is requisite. Now, to prepare the acetate of baryta employed, the author heats a mixture of sulphate of baryta (common heavy-spar) broken into small fragments, and charcoal, which gives him sulphide of barium. This dissolved in water is boiled with oxide of copper, forming hydrate of baryta and sulphide of copper. The solution of hydrate of baryta decanted off from the insoluble sulphide of copper, is saturated with acetic acid, and produces the solution of acetate of baryta employed as above. The sulphide of copper is transformed by roasting into oxide of copper, which serves again, &c.

If it is not essential to have the acetate of lead perfectly pure, instead of acetate of baryta *acetate of lime* may be used to decompose the sulphate of lead. For 100 parts of the latter 52 parts of acetate of lime are required. The latter salt is formed in large quantities in the manufactories of acetic acid, and if employed with care to decompose the sulphate of lead, very little lime passes into the solution of acetate of lead obtained.

II. ORGANIC CHEMISTRY.

On the Composition of several Essences.—Some years ago M. Biot submitted to M. Lallemand two vegetable products for examination. The first was the oil of the *Dryobalanops Camphora* collected by the well-known Dutch savaat Dr. Junguhn whilst journeying in the north-west of the island of Sumatra. The second, already known as *oil of camphor*, had been extracted from the *Laurus Camphora*, a plant which also furnishes the camphor of Japan. "The results at which I have arrived," says M. Lallemand[4], "differ with those already mentioned in works on chemistry, and render very probable the fact that the product analysed by M. Pelouze under the name of *essence of Borneo* had not been extracted from the *Dryobalanops Camphora* (the largest tree of the Indian Archipelago)." The researches contained in the author's paper show that the oil of Dryobalanops is a complex mixture analogous to the turpentine obtained from pines and firs. Its origin would make us suppose that it contained Borneo camphor: M. Lallemand assures us, however, that it does not contain a trace. The oil which exudes from the tree by incision does not differ from that obtained by decoction; they have both the same rotatory power and the same viscosity. The quantity experimented upon was too small to permit of further research. The camphor oil extracted from *Laurus Camphora* has already been analysed by Martius and Richer, who looked upon it as a first degree of oxidation of camphor, and represented it by the formula $C_{20}H_{16}O$. Gerhardt supposed it to be a mixture of camphor and a hydrocarbon, and M. Lallemand confirms this view.

"I have also determined," says the latter author, "the composition of some of the most abundant essences of the *Labiatæ* family, which I possessed in a pure state. The essentials oils of *rosemary*, of *common lavender* (*Lavandula spica*) and *cultivated lavender* consist of mixtures analogous to the oil of camphor, and show us to what extent the molecule $C_{20}H_{16}$ and its immediate derivatives are distributed throughout the vegetable world.

III. CHEMICAL ANALYSIS.

Separation and Determination of Phosphoric Acid.—M. Chancel[5] has published a new method for determining phosphoric acid when combined with protoxides. It is based upon the insolubility of the yellow phosphate of silver $3AgO.Po_5$, in a neutral liquid. The substance to be analysed is weighed, and dissolved in nitric acid; the solution is diluted with water; it is well not to employ too great an excess of nitric acid. To the clear liquid is added first a sufficient quantity of nitrate of silver, and then a slight excess of carbonate of silver. The saturation of the free nitric acid takes place rapidly without the application of heat; in a few moments the yellow phosphate of silver is thrown down. When the supernatant liquid no longer reddens litmus paper the precipitation is complete. The precipitate is collected on a filter and washed. When the washing is finished the filter is perforated with a platinum wire, and the whole of the precipitate washed out into a flask, and dissolved in nitric acid. The silver is then precipitated by hydrochloric acid, and in the filtrate the phosphoric acid is thrown down with an ammoniacal solution of sulphate of magnesia, and determined as usual.

Separation of Magnesia and Lithia.—M. Schaffgotsch showed some time ago[6] that magnesia can be separated from *potash* and *soda* by the following method. Neutral carbonates of ammonia and magnesia form together a double salt, which sesquicarbonate of ammonia precipitates at the ordinary temperature, when the solutions are concentrated and the sesquicarbonate in excess. This precipitate, which is first flocculent then granular, has for formula, $NH_4O, CO_2 + MgO.CO_2 + 4HO$—corresponding to 15·9 of magnesia in theory—experiment gave the author 15·5. The precipitate is almost insoluble in concentrated solutions of basic or neutral carbonate of ammonia. This insolubility has been turned to profit by the author to separate magnesia from potash and soda. It is, however, necessary to remark that after the washing, the double magnesian carbonate contains a notable quantity of carbonate of potash, but no carbonate of soda. It is therefore necessary to wash the residue of magnesia obtained by calcination, in order to eliminate this carbonate of potash.

The same author has more recently[7] found that this method is perfectly applicable to the separation of magnesia and lithia; carbonate of lithia being easily soluble in carbonate of ammonia.

"	25,000 ceases.

considerably less sensible to Reinsch's test than arsenious acid.

ANTIMONY.

By Reinsch's process	140,000 times (the limit).
" "	20,000 pretty strong.

John Horsley.

ANSWERS TO CORRESPONDENTS.

A. P. S.—If our young correspondent were better acquainted with the recent literature of chemistry, he would find no difficulty in the terms nitrate of *potassium*, chlorate of *barium*, &c. to which he alludes. These expressions have been adopted by many chemists, especially by those who regard a salt as differing from an acid only by containing a metal (or other basic radical) in place of hydrogen. The formulæ HNO_6, KNO_6 are indeed the simplest ways of writing the nitrate of hydrogen (nitric acid), and the nitrate of potassium, respectively.

With regard to *A. P. S.*'s second query:—Chloride of potassium is not so soluble a salt as he seems to imagine; he has forgotten also, that if in a liquid a larger amount of any salt whatever be produced than the liquid present can dissolve, a precipitate of that salt necessarily occurs.

Y. W.—Mr. R. A. Brooman is a patent agent at 166 Fleet Street.

W. H. F. H. will find the information he requires in Williams'Chemical Manipulations. We will think over the suggestion, which, however, has been partly anticipated by the publication of Dr. Faraday's lectures.

L. G. N. F.—Amateur (Glasgow)—received. Answers next week.

A. Subscriber.—Mr. Dougall's disinfecting powder is composed of carbolate of lime, with sulphite of lime and magnesia.

R. C. P.—The disinfecting property of earth is no doubt principally owing to the humus, a body of variable composition, but of highly absorbant powers.

J. G. F. R.—We know of none; but will inquire.

*** All *Editorial Communications* are to be addressed to the EDITOR; and *Advertisements* and *Business* communications to the PUBLISHER, at the Office; 12 and 13 Red Lion Court, Fleet Street, London, E.C.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On Various Methods for the Estimation of Copper, by FREDERICK FIELD.

[SECOND PART, *continued from* p. 63.]

C. MOHR precipitates metallic copper from its neutral solution by means of metallic iron.

$$CuO.SO_3 + Fe = FeO.SO_3 + Cu.$$

and estimates the amount of iron in the protosulphate by permanganate of potash. The solution is made very slightly acid, and chloride of sodium added. Too much heat is avoided during precipitation, as basic persalts of iron are thrown down at an elevated temperature. This method, when performed with care, according to Mohr, gives accurate results. I have always met with difficulties in its execution, as an excess of acid, however slight, necessarily gave results too high by an excessive formation of chloride of iron; and when no acid was present basic salts were formed in such a quantity as to yield an apparent loss of copper.

FLEITMANN precipitates the copper by metallic iron in the same manner as Mohr: washes the precipitate, and dissolves in perchloride of iron.

$$Fe_2Cl_3 + Cu = 2\ FeCl + CuCl.$$

The iron is determined, as before, by permanganate of potash. The results are very accurate.

In both the above processes much time and labour are doubtless spent in vain. It is far easier and quite as exact (more so, indeed, than in Mohr's method) to weigh the precipitated copper after washing and drying, if the precautions already advised have been followed, than to redissolve it, and estimate an equivalent of iron. If two equal weights of sulphate of copper, for example, are taken, dissolved in water, acidified, and precipitated by iron; in one case the copper is simply washed, dried, and weighed, and in the other it is redissolved in perchloride of iron, and the protochloride of that metal determined. Both the simple precipitation process and Fleitmann's give equally satisfactory results; but the former has the advantage of being more expeditious and less complicated.

Mohr's process will be seen at once to be perfectly inadmissible in the assay of the great bulk of copper minerals, unless he separates the copper by a preliminary operation, as iron is invariably present.

STRENG'S METHOD.—The oxide of copper is reduced to suboxide by grape sugar, a solution of starch and iodide of potassium added, and afterwards a standard solution of bichromate of potash, until a permanent blue colour is produced.

$$3\ Cu_2O + Cr_2O_6 = 6\ CuO + Cr_2O_3.$$

Dr. Streng takes advantage of the fact that bichromate of potash expels iodine from hydriodic acid, and the former then gives a blue colour with starch paste, in case no reducing substance is present. Thus no permanent blue can be formed as long as any subchloride of copper exists; but when the whole is converted into protochloride by the decomposition of the chromic acid, the blue iodide of starch remains. This method yields accurate results, but caution is required in the addition of the iodide of potassium. Diniodide of copper is excessively insoluble in hydrochloric acid unless the latter be in great excess, so that when a considerable quantity of the alkaline iodide is employed, and little hydrochloric acid is present, there is not much dichloride of copper in solution. The formation of the green sesquichloride of chromium also interferes disagreeably with the blue colour of the iodide of starch, rendering it difficult to tell when that compound is permanently produced. Dr. Streng has proved by many experiments that grape sugar in the cold has little or no reducing power upon bichromate of potash.

LEVAL'S process consists in placing a plate of metallic copper in an ammoniacal solution of oxide of copper until the latter becomes colourless,

$$CuO.NH_4O + Cu = Cu_2O.NH_4O.$$

the loss the copper has sustained corresponding to the quantity of copper originally in solution. The method is exact, but very tedious.

MM. PLESSY and MOREAU form a protochloride of copper as nearly neutral as possible by the addition of ammonia and the subsequent employment of hydrochloric acid, so as just to remove the blue colour and to present the well-known green of chloride of copper; and boiling this solution with a strip of metallic copper until it becomes colourless,—the loss of weight indicates the amount of metal in the chloride.

$$CuCl + Cu = Cu\ 2Cl.$$

In the notice of this method in the *Chemical Gazette*, in one of the numbers for 1859, it is said that iron interferes in the reaction, as metallic copper in solutions of salts of iron and copper reduces the copper to its minimum whilst the iron is at its maximum of oxidation.

This is probably an error of translation, as the reduction of persalts of iron to protosalts by copper is known to every one; and, in fact, one or two processes quoted above depend upon its reducing action.

Mr. E. O. BROWN dissolves the cupreous compound in nitric acid, adds carbonate of soda, and afterwards acetic acid in excess. Iodide of potassium is then added, equal at least to six times the weight of the copper. A standard solution of hyposulphite of soda is poured into the flask from a burette until the brown colour nearly disappears. Clear starch liquid is then introduced, and a further addition of the hyposulphite, until the blue colour is destroyed. This process, which yields most accurate results, fails to do so in the presence of peroxide of iron, not only, as Mr. Brown remarks, on account of the deep colour of peracetate of iron, but more particularly because the peroxide becomes partially deoxidised by the hyposulphite, and thus the reaction is interfered with. The estimation of copper in many alloys, &c. is by this method very rapid and trustworthy.

JACQUELIN has proposed to determine the amount of copper by means of a comparison of the intensity of blue in its ammoniacal solution. A series of tubes are

arranged, containing certain weights of oxide of copper in ammonia, and the blue colours are compared. Although useful in the estimation of copper in slags and other poor metallurgic products, it can hardly be admitted as more than an approximative assay.

Mr. David Forbes (*Jameson's Edinburgh Journal*, 1853) estimates the sulphide of copper obtained by precipitation, by heating it to redness in a crucible, allowing the mass to cool, adding carbonate of ammonia, and again heating. By this means the sulphate of copper formed during the ignition is decomposed, and an oxide and subsulphide remain. As each of these compounds contains equal quantities of copper (Cu_2S=80 % Cu, and CuO=80 % Cu), it does not matter in what proportion they may be formed during the ignition. Mr. Forbes found it impossible to obtain accurate results without the use of carbonate of ammonia, as the sulphuric acid requires an intense heat for its entire expulsion. Mr. Mitchell had years before used carbonate of ammonia in calcining sulphides of copper for the same purpose (see *Manual of Assaying*, 1st edition, 1846), and I have found it extremely advantageous, although its utility is doubted by Mr. J. A. Phillips (see *Metallurgy, Copper Assay*).

Mr. L. Rivot founds a process for the estimation of copper upon the insolubility of the subsulphocyanide of that metal (Cu_2CyS_2), and the great solubility of all other sulphocyanides in acid fluids.

The copper and other metals are obtained in solution in hydrochloric acid, and deoxidised by sulphurous acid or sulphite of soda. A dilute solution of sulphocyanide of potassium is now added, and the precipitate collected, gently dried, and weighed. The determination can be checked by converting the sulphocyanide into disulphide (Cu_2S) by fusion with a little sulphur in a porcelain crucible, from which air is excluded.

In nearly all the determinations above cited, except the process of Mr. Parkes, and in some instances of Pelouze, it is indispensable to free the solution from iron. As this is a very serious obstacle to the facility, and what is of far greater importance, the correctness of the assay, it has been my endeavour to devise a plan whereby copper, although in solution with many other metals, and iron among the number, might be speedily and correctly determined. Cyanide of potassium, it must be remembered, although applicable in many instances, is of little or no service when nickel, cobalt, manganese, zinc, mercury, or silver, are present. When iodide of potassium is added to a solution of a protosalt of copper, it is well known that iodine is eliminated, and diniodide of copper formed; but when iodine is added to a subsalt of copper, the whole of the former unites with the metal, and if a solution of iodide of potassium containing free iodine be added to a cupreous salt, both the free iodine, as well as that in combination, unite with the copper. The least excess is made discernible by a solution of starch. The process, therefore, is simply as follows:—The solution of the compound, free from nitric acid, is thoroughly deoxidised by sulphite of soda, and all excess of sulphurous acid expelled by boiling with hydrochloric acid. When cold, a small quantity of starch water is added, and the ioduretted iodide of potassium poured into the flask from a burette. Diniodide of copper is precipitated, and where the two solutions touch, a bright blue ring is formed, which disappears upon agitation. The process is complete when the blue becomes permanent; the objection is that the diniodide of copper has a great influence upon the iodide of starch, rendering it much paler and more indistinct, and considerable practice is required to ascertain exactly the point when the colour is first produced. By placing the flask upon a sheet of white paper, the bluish shade becomes much more apparent. When a very large quantity of iron is in the compound, the blue colour disappears after some hours, as iodide of starch is decomposed, although very slowly, by protosalts of iron. This does not vitiate the results, however, as the iodine gives no blue (that is to say, no colour which lasts more than a few seconds) until all the copper is precipitated. Although much time has been expended upon the above process, it is submitted with diffidence, inasmuch as the blue tint is not nearly so decided as could be wished, and at present this method can scarcely be recommended as applicable for the estimation of copper. Both silver and mercury would interfere, but they are easily separated; the silver of course would remain as chloride when the compound was dissolved, and the mercury would be precipitated as subchloride upon the addition of sulphite of soda.

In reviewing this brief and rapid sketch of the various methods employed for the estimation of copper, it will appear evident, I think, that much must be left to the knowledge and experience of the manipulator. In a mixture of lead, arsenic, and copper, the cyanide process could be advantageously adopted, whilst the method of precipitation would be worthless, as all the metals would be reduced. Manganese and zinc do not, on the other hand, affect the precipitation of copper upon iron, but render the cyanide estimation valueless.

The writer, ignorant of what substances may be undergoing investigation in the hands of the operator, can but point out the various methods that may be useful. Which will answer his purpose best, the experimentalist must decide.

TECHNICAL CHEMISTRY.

Notices of some of the Patents taken out for the Preparation and use of the new Purple Dyes generally known as the "Mauve or Perkins' Purple, Harmaline, Violine, Purpurine, Roseine, &c." with Remarks upon them.

The superb and fast purple colours obtained by the action of bichromate of potash on aniline and its homologues, was discovered by Mr. W. H. Perkins. Dr. Hofmann's researches on aniline were doubtless the true cause of attention being drawn to that base as a substance from which results of practical importance were one day to be obtained; and in the hands of his pupil, the manufacture of aniline purple has become one of the most refined and beautiful manufactures known.

The tendency of aniline to yield colours when subjected to various processes of oxidation has long been known. Solutions of salts of aniline with the mineral acids when evaporated, generally colour the edges of the basins of a red or blue tint. The power of a solution of bleaching powder to develope a charming purple tint in even the weakest aqueous solution of aniline has for many years been known, and applied in the examination of organic bases as a test for the presence of that alkaloid. This reaction has been seized upon as the foundation of a patent granted to Joshua Taylor Beale and Thomas Nesham Kirkham, dated 13th May 1859. The following quotation from the specification will give a sufficient idea of the nature of the process.

"As examples of some of the more desirable modes of producing the improved dye according to our invention, we

give the following proportions and modes of operating: — We take one measure of aniline water saturated, and add thereto one measure of acetic acid, say of five strengths, and one measure of hypochlorite of lime, of, say, specific gravity 1010. The hypochlorite should be carefully added, in order to admit of producing the particular shades of violet blues required, as shades of varying depth may be produced by increasing or decreasing the proportion of the hypochlorite. After a while the dye will become lilac, and will dye lilac of various intensities, depending on the quantity of hypochlorite of lime and water that may be mixed with the dye. Instead of adding a solution of chlorine or hypochlorite of lime to the liquor, we sometimes pass chlorine gas through the latter, carefully watching the same during the process, in order to arrest the further supply of the gas when the desired effect has been produced on the liquor."

With reference to the above we consider that any process founded upon the action of hypochlorite of lime upon aniline must be of limited application. In the first place the presence of the bleaching powder would render it impossible for the fabric previously dyed with fugitive colours to be passed through the bath. In the next place it would interfere in many cases with the subsequent application of other colours. But there is a more serious difficulty owing to the sparing solubility of aniline in water, consequently the dye will always be in a very dilute state, and totally useless in practice as compared with the highly concentrated solution sold by Mr. Perkins, at 6*l.* the gallon. In the next place even the small quantity of aniline which exists in solution will not be totally converted into dye, so that enormous volumes of fluid, involving correspondingly large vessels will have to be employed to obtain a comparatively minute quantity of dye.

Several patents besides that last mentioned, have been taken out for producing aniline purple. Among the substances used to oxidise the aniline may be mentioned peroxide of lead, peroxide of manganese, and the green manganate of potash.

As regards the manganese and peroxide of lead, there are two patents for the use of these substances. The first, dated 7th May 1859, was granted to Richard Dugdale Kay. The last named patentee takes an acetate, sulphate or hydrochlorate of aniline, with excess of acid, and treats the salt with peroxide of manganese at a temperature of 212° F. until no further precipitate is obtained. The patentee also claims peroxide of lead or chloride of lime as oxidising agents. In this process a precipitate and liquid are obtained, both of which contain colouring matter, the latter is obtained from the precipitate by digestion in dilute sulphuric acid. The liquids are then mixed together, and the colouring matter and manganese precipitated by ammonia. The precipitate is then washed and dried, and the colouring matter extracted by weak alcohol or methylated spirit.

This patent does not give any process for separating the brown or resinous impurities which accompany the colouring matter, except by so reducing the strength of the spirit as to prevent it dissolving the former. We were aware long before seeing this patent that peroxide of manganese could be used for producing the colour, but the experiments made upon the subject by a distinguished Scotch chemist were, as we were informed, by no means satisfactory either as regarded the quantity or quality of the product. If the author of this process can substantiate his claim to the chloride of lime and peroxide of lead processes he plainly takes the wind out of the sails of the patents granted to Beale and Kirkham, on the 13th and David S. Price on the 25th May 1859. The latter chemist in his provisional specification claims peroxide or sesquioxide of manganese, but in his final specification he does not mention the manganese, but confines himself to the lead process. Mr. Price, by oxidising aniline and its homologues with peroxide of lead, prepares three colours which he terms "Violine," "Purpurine," and "Roseine." For these he uses the following proportions of the ingredients: —

Violine. — 1 equivalent of aniline, 2 equivalents of sulphuric acid, 1 equivalent of peroxide of lead.

Purpurine. — 2 equivalents of aniline, 2 equivalents of sulphuric acid, 1 equivalent of peroxide of lead.

Roseine. — 1 equivalent of aniline, 1 equivalent of sulphuric acid, two equivalents of peroxide of lead.

The substances are boiled together and filtered hot. The colouring matters are contained in solution. The two first processes do not convert all the aniline into colouring matter, the last does. It is evident, therefore, that the redness of tint increases with the extent of the oxidation. This is quite in accordance with what has been observed generally with the colours from aniline and its congeners. We must admit that while Price's patent appears the most practical of the three, we do not think his process by any means approaching in value to that due to the talent of Mr. Perkins. It is true that the colours would be yielded of considerable purity, but the expense of the peroxide of lead would be very great, and the yield probably small. Moreover there are considerable difficulties in manipulating with so dense a powder as peroxide of lead. All the machinery for agitation must be strong and kept ceaselessly in motion or so heavy a precipitate would sink to the bottom and produce no result.

The process of Mr. Perkins has none of the disadvantages of any of the others; it is simple, practical, and yields an invariable product. It is true that it is said to require expensive and complex machinery in order to carry it out effectively; but as long as a process contains within itself the elements of success (which we do not think these new patents do), a little expense in the construction of machinery is of comparatively little moment where the final product is so valuable.

Williams's patent is for the use of the green manganate (or, as it is often incorrectly called in commerce, permanganate) of potash as the agent of oxidation. The product when the operation is properly conducted, is unexceptionable in purity and beauty. If the action be too much prolonged the colour is entirely changed, and a beautiful pink or crimson colour results. In fact, according to the specification, a certain amount of the pink colour is always produced. In carrying out this patent, the only thing to be considered is the price of the manganate and the quantity of the product. Upon this point we are not in possession of sufficient information to speak positively.

In using these dyes much depends upon the proper selection of the mordants. Tin is the only metal which has yielded unexceptionable results. The perchloride does very well, but stannate of soda is preferred. In printing, the dye is first mixed with gum, and the coloured mucilage is subsequently stirred up with the desired quantity of albumen. The printed fabric is then steamed in order to fix the colour.

Messrs. W. H. Perkins and Matthew Gray (the former the discoverer of the purple, and the latter the skilful director of the great printing establishment at Dalmonach near Glasgow), have taken out a patent for a new method of mordanting for the purple. They effect this by means of oxide or carbonate of lead. The acetate of lead is first printed on, and the fabric is afterwards

through a bath of ammonia, or an alkaline carbonate. By this means the lead becomes fixed in the fibre of the cloth. The purple dye bath should then yield its colour to the mordanted portions, to the exclusion of the other. But it is found in practice that the patterns printed in this manner are not sharp or well defined. The purple runs into those parts of the cloth which should remain white. To prevent this the goods are washed with soap and water after the fixation of the lead, before subjection to the bath; this clears the whites to some extent, but the patentees sometimes add soap to the bath itself, so as to purify the whites. But if the quantity of soap employed at first to wash the mordanted cloth has been in the proportion of one pound to twenty-five yards of cloth, they do not put any amongst the colour in the bath.

It is evident that this process contains within itself sources of error. By the necessity for soaping after the mordanting it appears that the lead does not adhere with sufficient firmness to the spot where it has been printed on, the soap is therefore to remove the feebly attached portions of mordant and prevent the colour from passing its proper limits. If, however, the first soaping has been insufficiently performed the dye spreads. This can to some extent be avoided by the objectionable process of putting soap into the dye bath. The patentees also put oily or fatty matters into the bath to prevent the spreading of the colour. We have reason to believe that this patent process is not successful in practice.

PHARMACY, TOXICOLOGY, &c.

On the Amount of Cantharidin contained in different Parts of the Body of the Cantharis vesicatoria, by M. Ferrer.[1]

Various opinions have been expressed on the question whether the cantharidin is equally distributed all through the body of the insect, or whether it exists only in certain parts to the exclusion of the others. Pliny, Galen, and Aetius believed that the elytra had no action. Hippocrates recommended that the head with its antennæ, the elytra, the membranous wings, and legs should be rejected, as he considered them completely inert. This opinion was adopted by Schwilgué in the third edition of his *Materia Medica*, which appeared in 1818. Latreille, Cloquet, and Audoin, on the contrary, assert that all parts of the body contain cantharidin.

In 1826, M. Farines, a pharmacien at Perpignan, having tried, without effect, plasters prepared separately with the powder of the elytra, wings, antennæ, and legs, returned to the opinion of Hippocrates, and in a note addressed to the Société de Pharmacie of Paris laid down the following conclusions:—

1. That the active part resided only in the soft organs.
2. That the hard organs do not possess any vesicating power.

In 1855, M. Courbon, in a memoir presented to the academy, also said that the vesicating principle of cantharides resided only in the soft or internal parts; but in opposition to M. Farines he contended that the soft parts of all regions possessed a vesicating property: that the soft or internal parts of the legs and head are as active as those of the thorax and abdomen, and that the only parts of the body completely inert are the elytra, the antennæ, and the portions of the feet composed only of hard parts.

[1] *Répertoire de Pharmacie.*

In 1856, M. Berthoud sought chemically for cantharidine: 1, in the abdomen and thorax, which he designated the *soft parts* of the flies; and 2, in the elytra, wings, antennæ, and feet, which he called the horny parts:

250 grammes of the abdomen and thorax gave 0·45 of cantharidin.

125 grammes of the horny parts gave 0·053.

These results, completely opposed to the conclusions of M. Farines, do not, however, demonstrate the existence of cantharidin in every part of the body of the fly. They only serve to confirm the opinion and the observations of M. Courbon. The parts which M. Berthoud has named collectively the horny parts, and from which he has extracted the cantharidin, contain in their interior a certain quantity of soft parts (the soft parts of the head and legs) and the cantharidin might be obtained exclusively from these soft parts if the observations of M. Courbon were strictly true.

On a question so interesting and as it appeared to me so imperfectly resolved, I thought it would be useful to make some new researches. To ascertain whether cantharidin is indifferently distributed over every part of the body, or whether it is only contained in particular parts, I have sought for it;—1, in the feet and legs; 2, in the head; 3, in the elytra and wings; and 4, in the thorax and abdomen.

First experiment:—11 grammes of the feet and legs were powdered and treated in a displacement apparatus with 25 grammes of chloroform; after macerating for three days the liquid was run off and the chloroform displaced by means of alcohol. The chloroform so obtained was allowed to evaporate in the air, and the residue was placed between folds of blotting paper to absorb the oil. The crystals left were redissolved in a small quantity of chloroform, again crystallised and then weighed. From the 11 grammes of the feet, 0·01 of cantharidin was obtained, still stained with a little of the green oil.

Second experiment:—17 grammes of the head and antennæ (there were very few antennæ) were treated with 35 grammes of chloroform, like the preceding, and from them 0·015 of cantharidin was obtained.

Third experiment:—11 grammes of the elytra and membranous wings were treated with 25 grammes of chloroform, and yielded 0·009 of cantharidin.

Fourth experiment:—30 grammes of the thorax and abdomen were mixed in a displacement apparatus with 70 grammes of chloroform. In this experiment the residue obtained by the spontaneous evaporation of the chloroform, furnished a large quantity of crystals. After having absorbed the oil and redissolved the crystals in a small quantity of chloroform, I threw the solution on a filter. After filtration I opened the paper and found it covered with small micaceous crystals of cantharidin perfectly white. The chloroform had deposited the crystals as it evaporated, and the green oil had passed through with the chloroform which had not evaporated. As this last portion might still contain a small quantity of cantharidin, I evaporated and again dissolved it in a little chloroform, and threw it on a filter as before. After repeating this a third time I obtained all the cantharidin furnished by the 30 grammes of the thorax and abdomen perfectly white. It weighed 0·072 grammes.

The blisters produced on my arm by a very small quantity of the crystals obtained in my experiments, left no doubt of their nature. From these experiments the author draws the conclusion that the active principle of cantharides is found distributed over all parts of the body.

A New Method of preparing the Fer Réduit.

A process invented by M. D. Guicciardi[1] consists in precipitating a concentrated solution of pure sulphate of iron with a hot saturated solution of oxalic acid. The precipitated oxalate is then placed in a gun barrel and gently heated, and afterwards a constant current of dry hydrogen is passed. Towards the end of the operation the gun barrel must be brought to a cherry-red heat. Before removing the powder it must be allowed to get quite cold. Prepared in this way, the *fer réduit* is a light, blackish-grey powder, which quickly dissolves in water acidulated with sulphuric acid, and takes fire, becoming changed into oxide, under the influence of heat.

ROYAL INSTITUTION OF GREAT BRITAIN.

A Course of Six Lectures[1] *(adapted to a Juvenile Auditory), consisting of Illustrations of the Various Forces of Matter, i. e. of such as are called the Physical or Inorganic Forces — including an Account of their Relations to each other; by* M. Faraday, *D.C.L., F.R.S., Fullerian Professor of Chemistry, R. I., Foreign Associate of the Academy of Sciences, Paris, &c.*

Lecture III. (Jan. 4, 1860.) *Cohesion—Chemical Affinity.*

We will first of all return for a few minutes to one of the experiments which we made yesterday. You remember what we put together on that occasion?—Powdered alum and warm water; here is one of those basins; nothing has been done to it since then, but you will find on examining it that it no longer contains any powder, but a multitude of beautiful crystals. Here also are the pieces of coke which I put into the other basin, these have a fine mass of crystals about them. That other basin I will leave as it is; I will not pour the water from it, because it will show you that the particles of alum have done something more than merely crystallise together. They have pushed the dirty matter from them, laying it around the outside or outer edge of the lower crystals—squeezed out as it were by the strong attraction which the particles of alum have for each other.

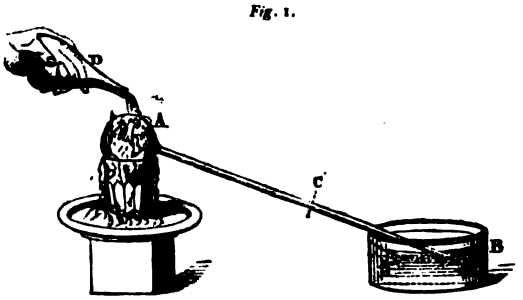
And now for another experiment. We have already gained a knowledge of the manner in which the particles of bodies—of solid bodies—attract each other, and we know that it makes calcareous spar, alum, and so forth, crystallise in these regular forms. Now let me gradually lead your minds to a knowledge of the means we have of making this attraction alter a little in its force; either of increasing, or diminishing, or apparently of destroying it altogether. I will take this piece of iron [a rod of iron about two feet long and a quarter of an inch in diameter], it has at present a great deal of strength, due to its attraction of cohesion; but if Mr. Anderson will make part of this rod hot in the fire, we shall then find that it will become soft, just as sealing-wax will when heated, and we shall also find that the more it is heated the softer it becomes. Ah! but what does *soft* mean? Why, that the attraction between the particles is so weakened that it is no longer sufficient to resist the power we bring to bear upon it. [Mr. Anderson handed to the Lecturer the iron rod, with one end red-hot, which he showed could be easily twisted aboutwith a pair of pliers.] You see, I now find no difficulty in bending this end about how I like; whereas I cannot bend the cold part at all. And you know how the smith takes a piece of iron and heats it, in order to render it soft for his purpose: he acts upon our principle of lessening the adhesion ofthe particles, although he does not know exactly the terms in which we express it.

And now we have another point to examine; and this water is again a very good substance to take as an illustration (as philosophers we call it all water, even though it be in the form of ice or steam). Why is this water hard? [pointing to a block of ice] because the attraction of the particles to each other is sufficient to make them retain their place in opposition to force applied to it. But what happens when we make the ice warm? Why, in that case we diminish to such a large extent the power of attraction that the solid substance is destroyed altogether. Let me illustrate this: I will take a red-hot ball of iron [Mr. Anderson by means of a pair of tongs handed to the Lecturer a red-hot ball of iron, about two inches diameter] because it will serve as a convenient source of heat [placing the red-hot iron in the centre of the block of ice]. You see I am now melting the ice where the iron touches it. You see the iron sinking into it, and while part of the solid water is becoming liquid, the heat of the ball is rapidly going off. A certain part of the water is actually rising in steam—the attraction of some of the particles is so much diminished that they cannot even hold together in the liquid form, but escape as vapour. At the same time you see I cannot melt all this ice by the heat contained in this ball. In the course of a very short time I shall find it quite cold.

Here is the water which we have produced by destroying some of the attraction which existed between the particles of the ice, for below a certain temperature the particles of water increase in their mutual attraction and become ice; and above a certain temperature the attraction decreases and the water becomes steam. And exactly the same thing takes place with platinum, and nearly every substance in nature; if the temperature is increased to a certain point it becomes liquid, and a further increase makes it a gas. Is it not a glorious thing for us to look at the sea, the rivers, and so forth, and to know that this same body in the northern regions is all solid ice and ice-bergs, while here in a warmer climate it has its attraction of cohesion so much diminished as to be liquid water. Well, in diminishing this force of attraction between the particles of ice, we made use of another force, namely, that of *heat*, and I want you now to understand that this force of heat is always concerned when water passes from the solid to the liquid state. If I melt ice in *other* ways I cannot do without heat; (for we have the means of making ice liquid without heat; that is to say, without using heat as a *direct* cause). Suppose, for illustration, I make a vessel out of this piece of tin foil [bending the foil up into the shape of a dish]. I am making it metallic, because I want the heat which I am about to deal with to pass readily through it;—and I am going to pour a little water on this board, and then place the tin vessel on it. Now if I put some of this ice into the metal dish, and then proceed to make it liquid by any of the various means we have at our command, it still must take the necessary quantity of heat from something, and in this case it will take the heat from the tray, and from the water underneath, and from the other things round about. Well, a little salt added to the ice, has the power of causing it to melt, and we shall very shortly see the mixture become quite fluid, and you will then find that the water beneath will be frozen—frozen because it has been forced to give up that heat which is necessary to keep it in the liquid state, to the ice on becoming liquid. I remember once, when I was a boy, hearing of a trick in a country alehouse; the point was how to melt ice in a quart pot by the fire, and freeze it to the stool. Well, the way they did it was this: they put some pounded ice in a pewter pot and added some salt to it, and the consequence was that when the salt was mixed with it the ice in the pot melted (they did not tell me anything about the salt, and they set the pot by the fire, just to make the result more mysterious), and in a short time the pot and the stool were frozen together, as we shall very shortly find it to be the case here, and all because salt has the power of lessening the attraction between the particles of ice. Here you see the tin dish is frozen to the board, I can even lift this little stool up by it.

This experiment then cannot, I think, fail to impress upon your minds the fact, that whenever a solid body loses some of that force of attraction by means of which it remains solid, heat is absorbed; and if, on the other hand, we convert a liquid into a solid, *e. g.* water into ice, a corresponding amount of heat is given out. I think an experiment of this kind will serve to show you this. Here (*fig.* 1.) is a bulb A, filled with air, the tube from which dips into some coloured liquid in the vessel B. And I

Fig. 1.

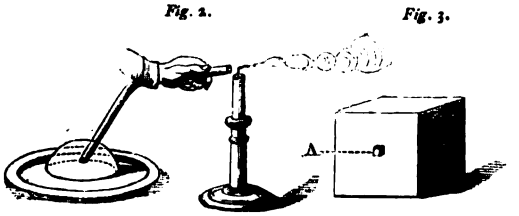


[1] Reported verbatim by special permission.

dare say you know that if I put my hand on the bulb A, and warm it, the coloured liquid which is now standing in the tube at C will travel forward. Now we have discovered a means, by great care and research into the properties of various bodies, of preparing a solution of a salt which if shaken or disturbed will at once become a solid; and as I explained to you just now (for what is true of water is true of every other liquid), by reason of its becoming solid, heat is evolved, and I can make this evident to you by pouring it over this bulb;—there! it is becoming solid, and look at the coloured liquid, how it is being driven down the tube, and how it is bubbling out through the water at the end; and so we learn this beautiful law of our philosophy, that whenever we diminish the attraction of cohesion we absorb heat—and whenever we increase that attraction heat is evolved. This then is a great step in advance, for you have learned a great deal in addition to the mere circumstance that particles attract each other. But you must not now suppose that because they are liquid they have lost their attraction of cohesion; for here is the fluid mercury, and if I pour it from one vessel into another I find that it will form a stream from the bottle down to the glass—a continuous rod of fluid mercury, the particles of which have attraction sufficient to make them hold together all the way through the air down to the glass itself: and if I pour water quietly from a jug I can cause it to run in a continuous stream in the same manner. Again, let me put a little water on this piece of plate glass, and then take another plate of glass and put it on the water; there! the upper plate is quite free to move, gliding about on the lower one from side to side; and yet, if I take hold of the upper plate and lift it up straight, the cohesion is so great that the lower one is held up by it. See how it runs about it as I move the upper one, and this is all owing to the strong attraction of the particles of the water. Let me show you another experiment. Suppose I take a little soap and water—not that the soap makes the particles of the water more adhesive one for the other, but it certainly has the power of continuing in a better manner the attraction of the particles; (and let me advise you, when about to experiment with soap bubbles to take care to have everything clean and soapy). I will now blow a bubble, and that I may be able to talk and blow a bubble too, I will take a plate with a little of the soapsuds in it, and will just soap the edges of the pipe, and blow a bubble on to the plate. Now, there is our bubble. Why does it hold together in this manner? Why, because the water of which it is composed has an attraction of particle for particle:—so great, indeed, that it gives to this bubble the very power of an india-rubber ball; for you see, if I introduce one end of this glass tube into the bubble that it has the power of contracting so powerfully as to force enough air through the tube to blow out a light (*fig.* 2.)—there is a light blown out. And look! see how the bubble is disappearing, see how it is getting smaller and smaller.

There are twenty other experiments I might show you to illustrate this power of the cohesion of the particles of liquids. For instance, what would you propose to me if, having lost the stopper out of this alcohol bottle, I should want to close it speedily with something near at hand. Well, a bit of paper would not do, but a piece of linen cloth would, or some of this cotton wool which I have here. I will put a tuft of it into the neck of the alcohol bottle, and you see when I turn it upside down, that it is perfectly well stoppered so far as the alcohol is concerned; the air can pass through but the alcohol cannot. And if I were to take an oil vessel this plan would do equally well, for in former times they used to send us oil from Italy in flasks stoppered only with cotton wool (at the present time the cotton is put in after the oil has arrived here, but formerly it used to be sent so stoppered.) Now if it were not for the particles of

Fig. 2. *Fig.* 3.



liquid cohering together, this alcohol would run out, and if I had time I could have shown you a vessel with the top, bottom and sides altogether formed like a sieve, and yet it would hold water owing to this cohesion.

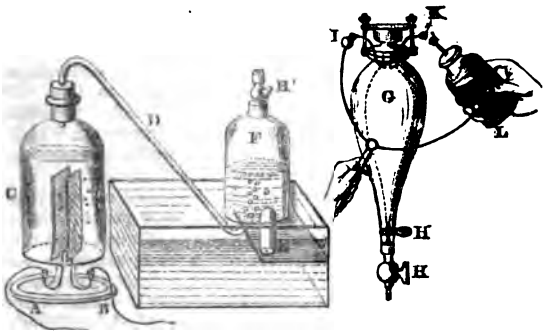
You have now seen that the solid water can become fluid by the addition of heat, owing to this lessening the attractive force between its particles, and yet you see that there is a good deal of attractive force remaining behind. I want now to take you a step beyond that. We saw that if we continued applying heat to the water (as indeed happened with our piece of ice here) that we did at last break up that attraction which holds the liquid together, and I am going to take some ether (any other liquid would do, but ether makes a better experiment for my purpose,) in order to illustrate what will happen when this cohesion is broken up. Now this liquid ether, if exposed to a very low temperature, will become a solid, but if we apply heat to it, it becomes vapour, and I want to show you the enormous bulk of the substance in this new form:—when we make ice into water, we lessen its bulk, but when we convert water into steam, we increase it to an enormous extent. You see it is very clear that as I apply heat to the liquid I diminish its attraction of cohesion—it is now boiling, and I will set fire to the vapour, so that you may be enabled to judge of the space occupied by the ether in this form by the size of its flame, and you now see what an enormously bulky flame I get from that small volume of ether below. The heat from the spirit lamp is now being consumed, not in making the ether any warmer, but in converting it into vapour, and if I desired to catch this vapour and condense it (as I could without much difficulty), I should have to do the same as if I wished to convert steam into water and water into ice: in either case it would be necessary to increase the attraction of the particles, by cold or otherwise. So largely is the bulk occupied by the particles increased by giving them this diminished attraction, that if I were to take a portion of water a cubic inch in bulk (A *fig.* 3.) I should produce a volume of steam of that size B [1700 cubic inches; nearly a cubic foot], so greatly is the attraction of cohesion diminished by heat; and yet it still remains water. You can easily imagine the consequences which are due to this change in volume by heat—the mighty powers of steam and the tremendous explosions which are sometimes produced by this force of water. I want you now to see another experiment which will perhaps give you a better illustration of the bulk occupied by a body when in the state of vapour. Here is a substance which we call iodine, and I am about to submit this solid body to the same kind of condition as regards heat that I did the water and the ether [putting a few grains of iodine into a hot glass globe, which immediately became filled with the violet vapour], and you see the same kind of change produced. Moreover, it gives us the opportunity of observing how beautiful is the violet-coloured vapour from this black substance, or rather the mixture of the vapour with air (for I would not wish you to understand that this globe is entirely filled with the vapour of iodine).

If I had taken mercury and converted it into vapour (as I could easily do), I should have a perfectly colourless vapour, for you must understand this about vapours, that bodies in what we call the vaporous, or the gaseous state, are always perfectly transparent, never cloudy or smoky; they are however often coloured, and we can frequently have coloured vapours or gases produced by colourless particles themselves mixing together, as in this case [the Lecturer here inverted a glass cylinder full of binoxide of nitrogen over a cylinder of oxygen, when the dark red vapour of hyponitric acid was produced]. Here also you see a very excellent illustration of the effect of some power of nature which we have not yet come to, but which stands next on our list—Chemical Affinity. And thus you see we can have a violet vapour or an orange vapour, and different other kinds of vapour, but they are always perfectly transparent, or else they would cease to be vapours.

I am now going to lead you a step beyond this consideration of the attraction of the particles for each other. You see we have come to understand that (to take water as an illustration) whether it be ice, or water, or steam, it is always to be considered by us as water. Well, now prepare your minds to go a little deeper into the subject. We have means of searching into the constitution of water beyond any that are afforded us by the action of heat, and among these one of the most important is that force which we call voltaic electricity, which we used at our last meeting for the purpose of obtaining light, and which we carried about the room by means of these wires. This force is produced by the battery behind me, to which however I will not now refer more particularly; before we have done we shall know more about this battery, but it must grow up in our knowledge. Now here (*fig.* 4.) is a portion of water in this little vessel C, and besides the water there are two plates of the metal platinum, which are connected with the wires (A and B) coming outside, and

I want to examine that water, and the state and the condition in which its particles are arranged. If I were to apply heat to it you know what we should get, it would assume the state of

Fig. 4

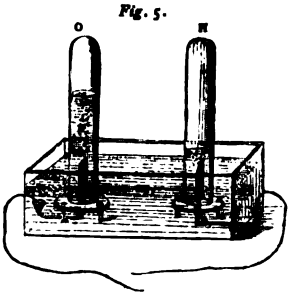


vapour, but it would nevertheless remain water, and would return to the liquid state as soon as the heat was removed. Now by means of these wires (which are connected with the battery behind me, and come under the floor and up through the table) we shall have a certain amount of this new power at our disposal. Here you see it is [causing the ends of the wires to touch]—that is the electric light we used yesterday, and by means of these wires we can cause water to submit itself to this power; for the moment I put them into metallic connexion (at A and B) you see the water boiling in that little vessel (C) and you hear the bubbling of the gas that is going through the tube (D). See how I am converting the water into vapour, and if I take a little vessel (E), and fill it with water, and put it in the trough over the end of the tube (D), there goes the vapour ascending into the vessel. And yet that is not steam, for you know that if steam is brought near cold water, it would at once condense, and return back again to water; this then cannot be steam, for it is bubbling through the cold water in this trough, but it is a vaporous substance, and we must therefore examine it carefully, to see in what way the water has been changed. And now in order to to give you a proof that it is not steam, I am going to show you that it is combustible, for if I take this small vessel to a light, the vapour inside explodes in a manner that steam could never do.

I will now fill this large bell-jar (F) with water; and I propose letting the gas ascend into it, and I will then show you that we can reproduce the water back again from the vapour or air that is there. Here is a strong glass vessel (G), and into it we will let the gas (from F) pass. We will then fire it by the electric spark, and then after the explosion you will find that we have got the water back again; it will not be much however, for you will recollect that I showed you how small a portion of water produced a very large volume of vapour. Mr. Anderson will now pump all the air out of this vessel (G), and when I have screwed it on to the top of our jar of gas (F), you will see upon opening the stopcocks (H' H H) the water will jump up, showing that some of the gas has passed into the glass vessel. I will now shut these stopcocks, and we shall be able to send the electric spark through the gas by means of the wires (I, K) in the upper part of the vessel, and you will see it burn with a most intense flash. [Mr. Anderson here brought a Leyden jar, which he discharged through the confined gas by means of the wires I, K.] You saw the flash, and now that you may see that there is no longer any gas remaining, if I place it over the jar and open the stopcocks again, up will go the gas, and we can have a second combustion; and so I might go on again and again, and I should continue to accumulate more and more of the water to which the gas has returned. Now is not this curious;—in this vessel (C) we can go on making from water a large bulk of *permanent gas*, as we call it, and then we can reconvert it into water in this way. [Mr. Anderson brought in another Leyden jar, which, however, from some cause would not ignite the gas. It was therefore recharged, when the explosion took place in the desired manner.] How beautifully we get our results when we are right in our proceedings!—it is not that Nature is wrong when we make a mistake. Now I will lay this vessel (G) down by my right hand, and you can examine it by and by: there is not very much water flowing down, but there is quite sufficient for you to see.

Another wonderful thing about this mode of changing the condition of the water is this—that we are able to get the separate parts of which it is composed, at a distance the one from the other, and to examine them, and see what they are like, and how many of them there are; and for this purpose I have here some more water in a slightly different apparatus to the former one (*fig.* 5.), and if I place this in connection with the wires of the battery (at A B) I shall get a similar decomposition of the water at the two platinum plates. Now I will put this little tube (O) over there, and that will collect the gas together that comes from this side (A), and this tube (H) will collect the gas that comes from the other side (B) and, I think we shall soon be able to see a difference. In this apparatus, the wires are a good way apart from each other, and it now seems that *each* of them is capable of drawing off particles from the water and sending them off, and you see that one set of particles (H) is coming off twice as fast as those collected in the other tube (O). Something is coming out of the water *there* (at H) which burns [setting fire to the gas], but what comes out of the water *here* (at O), although it will not burn, will support combustion very vigorously. [The Lecturer here placed a match with a glowing tip in the gas, when it immediately rekindled.]

Fig. 5.



Here then we have two things, neither of them being water alone, but which we get out of the water. Water is therefore composed of two substances different to itself, which appear at separate places when it is made to submit to the force which I have in these wires, and if I take an inverted tube of water and collect this gas (H), you will see that it is by no means the same as the one we collected in the former apparatus (*fig.* 4.). That exploded with a loud noise when it was lighted, but this will burn quite noiselessly—it is called *hydrogen*; and the other we call *oxygen*—that gas which so beautifully brightens up all combustion, but does not burn of itself. So now we see that water consists of two kinds of particles attracting each other in a very different manner to the attraction of gravitation or cohesion, and this new attraction we call *chemical affinity*, or the force of chemical action between different bodies; we are now no longer concerned with the attraction of iron for iron, water for water, wood for wood, or like bodies for each other as we were when dealing with the force of cohesion; we are dealing with another kind of attraction,—the attraction between particles of a *different* nature one to the other. Chemical affinity depends entirely upon the energy with which particles of *different* kinds attract each other. Oxygen and hydrogen are particles of different kinds, and it is their attraction to each other which makes them chemically combine and produce water.

I must now show you a little more at large what chemical affinity is. I can prepare these gases from other substances as well as from water; and we will now prepare some oxygen: here is another substance which contains oxygen—chlorate of potash; I will put some of it into this glass retort, and Mr. Anderson will apply heat to it: we have here different jars filled with water, and when by the application of heat the chlorate of potash is decomposed, we will displace the water, and fill the jars with gas.

Now when water is opened out in this way by means of the battery; which adds nothing to it materially, which takes nothing from it materially (I mean no *matter*, I am not speaking of *force*); which adds no *matter* to the water; it is changed in this way—the gas which you saw burning a little while ago, called *hydrogen*, is evolved in large quantity, and the other gas, *oxygen*, is evolved in only half the quantity, so that those two areas

1 Hydrogen	8 Oxygen	Oxygen . . . . . 88·9
		Hydrogen . . . . . 11·1
	9	Water . . . . . 100·0

represent water, and those are always the proportions between the two gases. But oxygen is sixteen times the

other — eight times as heavy as the particles of hydrogen in the water; and you therefore know that water is composed of nine parts by weight — one of hydrogen and eight of oxygen, thus:

Hydrogen . . .	46·2 cubic inches . .	= 1 grain.
Oxygen . . .	23·1 „ „ . .	= 8 grains.
Water . . (*steam*)	69·3 „ „ . .	= 9 grains.

Now Mr. Anderson has prepared some oxygen, and we will proceed to examine what is the character of this gas. First of all you remember I told you that it does not burn, but that it affects the burning of other bodies. I will just set fire to the point of this little bit of wood, and then plunge it into the jar of oxygen, and you will see what this gas does in increasing the brilliancy of the combustion. It does not burn, it does not take fire as the hydrogen would, but how vividly the combustion of the match goes on. Again, if I were to take this wax taper and light it, and turn it upside down in the air, it would in all probability put itself out, owing to the wax running down into the wick. [The Lecturer here turned the lighted taper upside down, when in a few seconds it went out.] Now that will not happen in oxygen gas; you will see how differently it acts (*fig.* 6.) [The taper was again lighted, turned upside down, and then introduced into a jar of oxygen.] Look at that! see how the very wax itself burns, and falls down in a dazzling stream of fire, so powerfully does the oxygen support combustion. Again, here is another experiment which will serve to illustrate the force, if I may so call it, of oxygen. I have here a circular flame of spirit of wine, and with it I am about to show you the way in which iron burns, because it will serve very well as a comparison between the effect produced by air and oxygen. If I take this ring flame, I can shake by means of a sieve the fine particles of iron filings through it, and you will see the way in which they burn. [The Lecturer here shook through the flame some iron filings which took fire and fell through with beautiful scintillations.] But if I now hold the flame over a jar of oxygen [the experiment was repeated over a jar of oxygen, when the combustion of the filings as they fell into the oxygen became almost insupportably brilliant], you see how wonderfully different the effect is in the jar, because there we have oxygen instead of common air.

Fig. 6.

(*The Fourth Lecture, on* Chemical Affinity *and* Heat, *will appear in our next.*)

NOTICES OF BOOKS, PATENTS, &c.

Letters on Modern Agriculture, by Baron Von Liebig. *Edited by* John Blyth, *M.D. Professor of Chemistry, Queen's College, Cork.*

On the Valuation of Soils, and the Nutrition of Plants, by Robert Galloway, *F.C.S. Professor of Practical Chemistry, Museum of Irish Industry.*

Hints to Practical Agriculturists, by E. B. Fowler.

Notwithstanding the large circulation for some years of works on agricultural chemistry, we believe that an intelligent knowledge of the subject has extended very little among the class whose especial business it immediately concerns. Nor have we far to look for the reason. Agriculture has been for centuries a mere empirical art, with which true scientific knowledge has had nothing whatever to do. Farmers have dug, and ploughed, and manured, simply because their fathers did so, and without troubling themselves in the least about the why and the wherefore. And the system has always answered to a certain extent. But conducted on such a plan, it is clear that agriculture could make no decided advance.

"The progress of every trade by mere empirical experience," says Liebig, "and also of that of agriculture, has a limit. Every experimental method comes to an end when the senses are no longer sufficient for the perception of facts; when no new circumstance is presented to the senses for perception; when in fact every thing has been tried, and the facts resulting from such trials have been adopted into the particular art or trade. Further progress can then only be looked for, if hidden facts are sought out, the senses are sharpened for their perception, and the means of investigation are improved."

But when the chemist comes with his improved means of investigation, he brings with him a science with which the farmer has no acquaintance; he employs a terminology to which a farmer can attach only the vaguest of meanings, and which is at times altogether unintelligible to him. No wonder then that the practical agricultural intellect sometimes looks on the chemist as a charlatan — a reputation which it must be confessed has been at times too well deserved. And yet nothing can be clearer than that if agriculture is to advance, it must be mainly by the assistance of chemistry. Deep drainage, deep ploughing, and more perfect disintegration of the soil, have been productive of much good; but the advantage of these processes has a limit which is soon reached. The fertility of the soil must ultimately depend on the supply of food for the plant grown upon it — that is upon the manure — and how can this be supplied intelligently without knowing, first what the plant requires, and then in what ingredients the soil is deficient.

But here unfortunately the chemist is soon at fault.

"Our knowledge," says Professor Galloway, "at the present time is very crude and limited in all that relates to soils, whether as to their capabilities or requirements; we do not know in what state the substances available for growing plants exist in soils; what the relative proportions, and in what amount must these plant-forming substances be present in order that the land may yield the greatest increase at the least cost. We are yet in doubt whether plants take up the mineral ingredients from the land in a fluid or a solid state. And we have yet to learn the chemical changes which take place between the soil constituents and the manurial substances when the latter are applied to the land. We can learn by the aid of chemical analysis whether a soil contains all the substances required by plants; but this is all the aid which chemistry affords us as regards soils. For if the analysed soil contain all the essential substances, the analysis conveys to us no information as regards the productive power of that soil. If it should prove fertile, we cannot in the majority of cases learn from the analysis upon what its fertility depends; if, on the other hand, it prove barren, whether it is its chemical or physical properties which require to be altered in order to render it fruitful."

It must not be imagined, however, that we are likely to remain long in this state of ignorance. No chemists of the present day are more active than those who devote themselves to the study of agricultural chemistry—not in the laboratory only — but in the fields where alone practical truth is to be acquired.

How much chemistry has done for agriculture up to the present time is a debateable point. Most practical farmers, we believe, would say with Mr. Pusey, that it has done nothing but give a receipt for increasing the efficacy of bones by the action of sulphuric acid, and proposing to employ flax water instead of liquid manure; and they would probably agree with the same gentleman that "it is utterly absurd to put any value on the doubtful precepts of chemistry." Baron Liebig's first letter too reads like a confession of failure, the blame of which, however, he is anxious to throw on the farmer. But if chemical science had done nothing more than point out the value of guano, it would have achieved a great work. We believe that it has already done much, and will do more; and that the time will soon come when the chemist will be the daily adviser of the farmer, as he is of the calico printer, the dyer, the gas manufacturer, and the brewer. In the meantime much has to be accomplished which we may safely leave to those engaged in the study.

Mr. Fowler's *Hints* contain some good advice for farmers; but some of his views have probably been modified since he published his little book. Professor Galloway's well-written paper is a valuable contribution, and we should be glad to see it published so that it may become better known. Liebig's letters have been extensively read, though we fear by che-

mists and amateurs, rather than practical agriculturists. It is gratifying to find that in this book the Baron does not advertise his patent manures.

In conclusion we cannot help quoting from the letters for the benefit of our medical readers the story of the "green" doctor of Offenbach, to whom, it must be premised, Liebig compares the practical agriculturist commencing his career.

"He was a Jewish physician of renown, who was called in to all dangerous cases of illness in Frankfort, Hanau, and the neighbourhood; and his practice was not without success. Nature had given him a quick eye and fine powers of observation. His knowledge was obtained in an hospital in which he acted as sick attendant. He used to accompany the physician through the sick wards, looked at the tongues and urine of the patients after him, felt their pulse, and superintended the orders about their diet. He copied the prescriptions regularly; marked them with a red cross when the patient recovered, and with a black one when he died. His sheets grew by degrees to the size of a book, and when nothing new presented itself to be added to it, he begun in the first instance to practice on a small scale, and then started on the full career of a physician. He was skilled in diagnosis, and had his prescriptions for the various cases. Those with the red crosses came first; and if unsuccessful, then followed the black. In this way he acquired his own experience. He was very orthodox, and on the Sabbath day would write no prescription, but would then dictate them in the apothecary's shop to the assistant. He commenced with 'Rrrrr' (this meant recipe, '*Tartaremet*, two grains' (*i. e.* tartari emetici grana duo); *syralth* (*i. e.* syrupus althese). He could not read h is own prescriptions, but his fame as a practical physician was so established that the regularly educated physicians in Offenbach could not succeed in putting an end to his career on the ground of his never having received a medical education."

Improvements in the Manufacture of Umbrellas, Parasols, Hats or Hat Covers, Caps, Capes, Coats, Mantles, Dresses, Gloves, and other similar articles. Stephen Barnwell and Alexander Rollason, 1859.

Collodion and castor oil have received a new application. Messrs. Barnwell and Rollason use the mixture for making silks and other woven fabrics waterproof. Their manner of proceeding is as follows:—"Assuming the material under operation to be silk, we take collodion and mix it with vegetable oil, such as either hempseed, rape, olive, almond, nut, poppy, castor, cotton, or linseed oil in the purest possible state, and we find that such oils when mixed with collodion undergo a change upon being subjected to heat, and this change or decomposition is highly advantageous in the subsequent processes to which the silk will be applied. The mixture of collodion and oil is spread or poured upon plates or cylinders of metal or glass, and before it is quite set the silk is laid or rolled over it and immediately removed, bringing away with it a thin film of collodion and oil. The silk thus coated is now removed to a stove or drying oven and submitted to a heat of 100° to 300° Fahrenheit, by which the mixture undergoes the before named change or decomposition, and the result is that a slightly glazed appearance is imparted to the silk, which is at the same time considerably strengthened or thickened, and may be rendered almost or quite opaque by the mixture of colouring or thickening matter with the collodion and oil. A thin silk is thus rendered equal in strength to a more costly one, and the quality of imperviousness to water, which the material possesses in a high degree, will be of service."

The patentees prepare their collodion with gun cotton or with xyloidine made from hemp, flax, jute, straw, sawdust, or starch, which they dissolve in any of the solvents of gun cotton and mix with any of the oils before mentioned, adding only so much of the oil or mixed oils as will be freely taken up by the solution. If they desire the coated silk or other fabric to be soft and pliable in its nature, they add a small quantity of animal oil to the solution. The proportions the patentees use for coating silk are 30 parts of the xyloidine dissolved in *about* 300 parts by weight of ether, with 100 parts of spirits of wine, with which is mixed from 75 to 100 parts of vegetable oils. This solution is allowed to evaporate in a still until it arrives at such a density that it will only just flow evenly over a glass plate, so as finally to leave a substantial film behind it.

If the patentees can make some light and inexpensive fabric waterproof, and at the same time soft and pliable, it would be extensively used by surgeons. Oiled silk is expensive, and the oiled calico and gutta percha tissue, sometimes used in its stead, lack the softness and pliability desired. The article we have suggested is greatly desired in our large hospitals.

Improvements in the preparations of certain colouring matters. R. D. Kay, 1859.

The patents for aniline dyes multiply very fast. The inventor of the present process mixes the aniline or similar product with an acid so as to form a salt, the base of which is the aniline or other similar material. An excess of acid is found better than a neutral proportion, and good results are obtained from acetic, hydrochloric, and sulphuric acids. When the last is used, 50 parts of aniline are mixed with 40 parts of the acid (sp. gr. 1·85) diluted with about 1400 parts of water. To this compound 200 parts of peroxide of manganese is added, and the whole is heated to 212° Fahr., and stirred until a precipitate is no longer produced.

The coloured solution is separated from the precipitate by filtration, and the precipitate is digested with more dilute sulphuric acid to dissolve any colouring matter it may contain. Ammonia is then added to the combined solutions to neutralise all the acid and precipitate the colouring matter and manganese. This precipitate is washed and dried, and the colouring matter is dissolved out with alcohol or methylated spirit. The inventor gives the name of *hurmaline* to the colouring matter. The process may be shortened by adding the alkali to the whole solution after the oxidation of the peroxide of manganese has been completed; but in this case the colouring matter must be extracted from the precipitate with alcohol diluted with about three parts of water to avoid dissolving the resinous or bituminous matter which may be mixed with it.

CORRESPONDENCE.

The Atomic Theory.

To the Editor of the Chemical News.

Sir,—The atomic theory has already been the subject of some dispute: still I venture to draw attention to it, because it appears to me to be to some extent inconsistent with itself; and it can scarcely be desirable that a false theory should hold ground, even though it may serve to explain some phenomena easily, because it might have a tendency to warp our ideas of the nature of matter, and it must be allowed that an easy explanation is dearly bought, if it be at the expense of truth.

In the atomic theory it is assumed that matter is not indefinitely divisible, but that, after a certain point, further division becomes impossible, not for want of means to carry the division to a greater extent, but because the particles into which the matter is divided are units in themselves, and by their nature cannot be divided; they are, in fact, atoms. Each of these atoms, it will be allowed, has a certain length, breadth, and thickness, and occupies a certain space. Since it occupies space, it must have different parts; for if we imagine the extremity of a plane of infinite tenuity to be placed so that it may be opposite to the centre of the atom and also touch it, there would clearly be a portion of the atom projecting on each side of the plane. If it did not do so, it would be a *point*, which has no magnitude, and therefore would no longer be an atom. It is evident from this, that an atom has different parts; and one would imagine that

these parts must be kept together by some law. According to the theory, the parts of the atom keep together because they are *one*, or, in other words, because they do. This is at best an unphilosophical method of explaining the constitution of an atom. Perhaps according to the theory, an atom has no constitution at all. In that case, it is difficult to imagine it to have any existence at all. If it is admitted that the different parts of the atom are held together by some law, it then ceases to be an atom. We have only to overcome this law, and the atom will separate.

Again; according to the theory, all forces such as attraction, &c. and motion, must exist *exterior* to the atom, and have nothing to do with its internal constitution; for it is inconsistent with the theory to imagine it to have any internal constitution. This being the case, what end is answered by the atom being there at all, for the material universe might go on just as well without it as with it. In short, why not adopt Faraday's theory of the existence of matter, or Berkeley's, of the non-existence of matter; for this last theory simply goes a step farther than Faraday's. The atomic theory viewed as a stepping-stone to these would seem to be philosophical. Taken alone it is difficult to understand in what respect it renders the explanation of chemical combination, &c. more simple than before. It appears to me rather to *hide* the difficulty than to explain it, for in what respect is it better to say one *atom* of H combines with one *atom* of O, and they together make one atom of HO; or to say one *equivalent* of H combines with one *equivalent* of O and they together make one *equivalent* of HO? When we express this reaction according to the atomic theory, we have done nothing more than remove the difficulty to the individual atoms, which can scarcely be considered as explaining the phenomenon.

In conclusion, I would make one observation with respect to what I have now written on this subject. In arguing this question with a scientific friend, we could not come to any conclusion, for this simple reason: he assumed the very point that I was endeavouring to raise a question upon, namely, the existence of an atom.—I am, &c.

GIMEL.

Chemical Notices from foreign sources, by Dr. T. L. PHIPSON.

I. MINERAL CHEMISTRY.

Nickel.—M. Charles Tissier has communicated to the Paris Academy of Sciences[1] a note upon some peculiar properties of nickel. This metal, which is placed near to iron in the electro-chemical tables of Berzelius, as also in the classification of metals in families by Ampère, is again brought near to the latter metal in M. Thénard's classification according to the affinity of metals for oxygen. However, although nickel resembles iron so closely by its atomic weight and by analogous compounds such as its salts, such is not the case when we consider nickel in other respects; thus it is generally supposed, on account of its place in the electro-chemical series, that nickel will precipitate copper from its solution as zinc and iron do. M. Tissier assures us, however, that no such phenomenon takes place. He has left pure fused nickel for 15 hours in a liquid containing a mixture of chloride of ammonium and sulphate of copper (1 part) and water (10 parts). At the end of this time no copper had been precipitated, and the piece of nickel which weighed 18·925 grammes before the experiment weighed exactly the same when it was terminated. A piece of bronze of aluminium placed in the same conditions has been found to lose 6 per cent. of its weight, and a piece of German silver more than 7 per cent.

All acids, save nitric acid, have only a weak solvent power on melted nickel. In 15 hours sulphuric acid diluted with twice its weight of water, only dissolved 0·032 grammes of 18 grammes submitted to its action. Strong hydrochloric acid only dissolved 0·15 grammes of the same quantity in the same time.

When these results are compared to those obtained with iron, zinc, copper, lead, and tin, it is seen how superior nickel is to these metals, and how much nearer it comes to silver; for like the latter it appears to be attacked with ease by nitric acid alone. According to M. Wertheim the tenacity of nickel is to that of iron as 90 is to 70. M. Tissier next informs us that nickel can be obtained in France, in the pure state, at 10 francs a pound (Eng.), or 20 francs the kilogramme, and that, at this price, with the properties it possesses, it is capable of many useful applications, among others that of serving in calico printing to take off the excess of colour or mordant from the cylinders. The bars at present used for this are of steel, which is soon attacked and destroyed by the sulphate of copper and other mineral substances employed as mordants or colours.

Bromide of Chromium.—MM. Wöhler and Bauck[2] have obtained bromide of chromium by passing a current of dry bromine into a red-hot tube containing small balls made of a mixture of charcoal, oxide of chromium, and starch—these balls were previously calcined.

Part of the bromide produced is volatilised beyond the mixture, and part remains in the latter forming crystalline laminæ. Bromide of chromium presents itself in hexagonal laminæ of a black colour, and with a semi-metallic lustre; seen by transparency these crystals appear of an olive green, and viewed in a certain direction they show also a feeble red tint. The powder they give is yellowish green. When heated in the air this bromide is transformed into green oxide. It is insoluble in water. The alkalies attack it easily. Hydrogen reduces it to a white bromide, even at a low temperature. M. Bauck has remarked that the violet-coloured sesquichloride of chromium becomes deliquescent when put in contact with tin, and soon gives a green liquid. The sesquibromide presents a similar property, the phenomenon being owing doubtless to a partial reduction of the salt, the protobromide formed in this circumstance causing the solution of the sesquibromide in the humidity of the atmosphere.

The analysis of the new substance which forms the subject of this paper has led M. Bauck to the formula Cr_2Br_3.

II. ORGANIC CHEMISTRY.

Urea in Chyle and in Lymph.—Guided by the idea that urea must be formed, not, as is sometimes thought, in the capillary bloodvessels, but in the interior of the tissues themselves, wherever the materials of the organism have become useless to life and are about to be eliminated by respiratory combustion, M. Wurtz[3] determined to seek for this substance in the chyle and in the lymph. The author in the first place examined the chyle of a bull upon which a fistula had been operated in the thoracic duct. He coagulated about 600 grammes of this liquid by means of heat; the filtered liquid was evaporated, the residue treated with absolute alcohol, and the alcoholic solution filtered and evaporated. The alcoholic extract thus obtained was treated with ether as long as anything dissolved; the ethereal solution left to itself soon furnished perfectly colourless crystals of urea. M. Wurtz afterwards found urea in the lymph of the dog, the cow, the bull, and the horse. In these cases he determined also the relative proportions of urea contained in the blood, the chyle and the lymph of the same animal by a combination of the methods proposed for determining urea by Liebig and Bunsen. The results obtained have been tabulated. The tables show that urea exists in the three liquids of a cow nourished on dry lucerne; 1000 grammes of the blood and 1000 grammes of the chyle containing 0·192 grammes of urea, the same quantity of lymph giving 0·193 grammes of urea.

On the Chemical Constitution of Cartilage.—Two distinct cartilaginous tissues are recognised in the animal world. The first constitutes the cartilage which forms the basis of the bones, *i. e.* which on being incrusted with

[1] *Comptes-Rendus*, 9 Jan. 1860.

[2] *Ann. der Chem. und Pharm.* t. cxi. p. 382.

[3] *Journ. de Pharm. et de Chimie*, Août 1859.

carbonate and phosphate of lime, forms the bony structures of the animal organism; this species is sometimes known as *collagenous*. The second, known as *hyalin cartilage* or *chondrogenous cartilage* is never transformed into bone. Up to the present time chondrogenous cartilage and collagenous cartilage have been looked upon as two distinct chemical varieties of the cartilaginous tissue. The collagenous cartilage obtained by the action of hydrochloric acid upon bones appear, in fact, to differ essentially from chondrogenous cartilage, which constitutes the hyalin cartilaginous tissue, or that cartilaginous tissue which is not yet penetrated with calcareous matter. The latter gives all the reactions which characterise *chondrine*; it is precipitated from its solutions by acetic acid, by acetate of lead, by alum, and by chloride of iron, whilst the former is not precipitated by these chemical agents, but only by tannic acid and corrosive sublimate.

Dr. Friedleben [4] does not deny these facts, but asserts that they are not sufficient to permit us to separate the two tissues as distinct varieties. These chemical differences result, according to the author, from the mode of preparation of the substances, and not from a primordial difference in the cartilaginous tissues. In fact, the chondrogenous tissue submitted for some time to the action of hydrochloric acid no longer gives the reactions of *chondrine*, but those which characterise *gelatine*, the basis of the collagenous tissues, in the same manner as the collagenous cartilage extracted from bones by hydrochloric acid. From this ingenious discovery it results that all the cartilaginous tissues of the animal economy present an identical constitution in a chemical point of view. It is well to add that some time time ago M. Schultze showed that caustic potash possessed the property of transforming chondrogenous tissues (chondrine) into collagenous cartilage (gelatine).

III. CHEMICAL ANALYSIS.

New Reagent for Alkaloids.— M. Schulze [5] has observed that if perchloride of antimony be added drop by drop to a solution of phosphoric acid a liquid is obtained which produces with ammoniacal salts, and with most of the alkaloids, precipitates similar to those which are formed by the phospho-molybdic acid of Sonnenschein; the following are the effects observed: —

Strychnine. — Solution of the nitrate at $\frac{1}{1000}$th abundant yellow caseous precipitate; at $\frac{1}{5000}$th white flocculent precipitate; at $\frac{1}{25000}$th slight turbidity.

Brucine.— Solution of the hydrochlorate at $\frac{1}{1000}$th a rose-coloured precipitate, soluble whilst warm, reprecipitated by cooling, leaving the supernatant liquid of a carmine red; at $\frac{1}{10000}$th the sesquichloride is still troubled, and the liquid takes a rose tint.

Quinine.—At $\frac{1}{1000}$th flocculent precipitate of a clearer colour than that of strychnine; at $\frac{1}{5000}$th the liquid becomes opalescent.

Cinchonine. — At $\frac{1}{1000}$th blue flocculent precipitate; at $\frac{1}{3000}$th slight turbidity.

Veratrine. — At $\frac{1}{1000}$th dirty white flocculent precipitate; at $\frac{1}{5000}$th the liquid becomes opalescent.

Narcotine.—At $\frac{1}{1000}$th copious yellow flocculent precipitate; at $\frac{1}{4000}$th turbidity; at $\frac{1}{25000}$th a turbidity in the liquid is still perceived.

Morphine.—At $\frac{1}{1000}$th the liquid is too dilute to produce a precipitate.

Codeine.—At $\frac{1}{1000}$th the turbid liquid takes a dirty brown colour.'

Nicotine.—At $\frac{1}{250}$th slight turbidity in the liquid.

Conine.—At $\frac{1}{250}$th liquid becomes slightly opalescent.

Piperine.—Yellow coloration even in diluted liquids.

Atropine.—At $\frac{1}{1000}$th caseous white precipitate, soluble in the warm liquid, completely thrown down again by cooling; at $\frac{1}{5000}$th slight turbidity, which becomes more sensible by long boiling.

Digitaline.—At $\frac{1}{1000}$th slight turbidity, which at first disappears by boiling, and then gives place to a voluminous precipitate.

Aconitine.—At $\frac{1}{1000}$th copious white precipitate; at $\frac{1}{5000}$th turbidity; at $\frac{1}{25000}$th liquid becomes opalescent.

Caffeine.—At $\frac{1}{1000}$th no reaction.

Theobromine. — At $\frac{1}{1000}$ slight muddiness.

SCIENTIFIC NOTES AND QUERIES.

Purification of Water by means of Metallic Oxides.—Sir,—Pray allow me a few words in reference to a letter in the Chemical News for Jan. 7 (p. 60), bearing the signature of *J. Horsley*, pointing out oxide of manganese as a deodorising and decolouring agent for water, and referring to a letter of mine in your previous number, in which I speak of my early use of oxide of iron for similar purposes.

When I discovered the purifying powers of oxide of iron several years ago, it would indeed have been great shortcoming on my part had I failed to examine how far other oxides possessed the same; knowing, as every chemist must, that no one body in nature possesses any signal property without it being shared by others. In a word, when any one body is noted as possessing a peculiar physical property, it may be predicated that others of its class possess the same, though in a decreasing ratio. Deeming it therefore more than probable that this power could hardly be confined to oxide of iron, my early experiments included an examination of every other oxide insoluble in water. These resulted in showing that a variety of such bodies were endowed with similar powers, though in less degree than oxide of iron. Accordingly, in the specification of one of my patents (that of 1857), where, after describing the purifying properties of oxide of iron, I also show that those of manganese, nickel, and cobalt, possess similar powers, though in a minor degree, at the same time, from its greater energy, its general freedom from impurity, and its cheapness, oxide of iron is preferably recommended in practice.

Your correspondent will therefore see that what he finds in 1860 was published by me in 1857. Nor was it difficult to foresee that the bare publication of such a fact with regard to the oxide of iron, would soon set a certain class of chemists to find some other oxide with similar properties, but without any acknowledgment as to the source from whence they were obviously indebted for the idea. Therefore it was that previous to my official publication, I felt it my duty to extend my experiments over the other oxides.

Though already published in my paper read at Aberdeen, an abstract of which you have, perhaps you will permit me to repeat here that the oxides of the whole list of magnetic metals, amounting to eleven, possess this purifying power in relative degree. And, what was less to be expected, the oxides of some of the dia-magnetic metals as well. Among the latter oxide of silver ranks high. Besides these, several gums, resins, and tars, exercise a similar power on oxygen.

As regards the action of these bodies in effecting the purification of water, they cause the oxygen present in it to combine with the colouring matter, and thus convert it into carbonic acid.

In deodorising water, the action is altogether different. The sulphur from which odour is chiefly derived is absorbed by the oxides, and when saturated may be distilled off by heat. If the deodorisation were effected by means of oxygen, it is clear sulphuric acid would be formed, which would necessarily combine with the iron to form a protosalt of that metal. Thus adding an impurity to the water, and consuming the purifying agent itself. The addition of chloride of lime, spoken of by your correspondent would entirely prevent the oxidising action necessary for decoloration, on the one hand, and add nothing to the sulphur absorbing power on the other.—*Thomas Spencer.*

Homœopathic Medicines: Sir,—Having recently been requested to analyse some homœopathic globules for arsenic, I took 4 bottles, amounting to 2400 globules when, on dissolving them in ½ oz. of water, not the slightest indication of arsenic was obtained by Reinsch's test. Now, supposing $\frac{1}{20}$th of a grain to have been diffused over the whole of these globules, then *each* would represent $\frac{1}{48000}$, which ought to have afforded strong indications of arsenic, the aggregate estimate of these globules at $\frac{1}{20}$ times each, only $\frac{1}{100}$th the amount capable of being detected (viz. a millionth) would be the astonishing sum of 2 billion, 304 million times, yet not a particle of arsenic was made to show itself. What strong faith people must have!—*J. Horsley.*

LABORATORY MEMORANDA.

On the Action of Hydrosulphuric Acid on Perchloride of Iron.—When hydrosulphuric acid gas is passed into a solution of sesquichloride of iron, a dark purple colour is produced by every bubble of the gas, rapidly disappearing, and followed by the deposition of sulphur. This reaction is more distinctly perceived when water saturated with hydrosulphuric acid is added to the sesquichloride of iron; a beautiful rich purple liquid is then produced, which is perfectly clear at first, but very speedily deposits sulphur, its purple colour rapidly fading, and forms the well known milky liquid. The colour is a little more permanent when the sesquichloride of iron is dropped into the solution of hydrosulphuric acid.

The presence of hydrochloric acid, even in large quantity, does not prevent the production of the purple colour, though a larger quantity of solution of hydrosulphuric acid must be added.

The reaction is obtained even with a dilute solution of the iron salt, but not with very dilute hydrosulphuric acid.

Some specimens of solution of hydrosulphuric acid did not exhibit this behaviour.

Water which had been boiled for half an hour was allowed to cool in a rapid stream of hydrosulphuric acid; the solution thus obtained gave a very faint purple colour with the iron salt. After standing for some minutes in an open flask, it was capable of giving a far more intense colour.

A solution of hydrosulphuric acid which had been shaken with air in a test tube, or into which air had been blown through a glass tube, did not give the purple colour, though much sulphur was deposited, on adding sesquichloride of iron.

It is well known that the hyposulphites give a purple colour with sesquichloride of iron, but this colour is much redder and less rich than that under consideration; moreover, it does not fade quite so rapidly, and its disappearance is not attended with deposition of sulphur.—*C. L. B.*

MISCELLANEOUS.

Case of Poisoning by White Precipitate, at Petworth.—The name of the unfortunate person involved in this painful case is Harriet Moore, certainly not more than twenty years old. She was an inmate of the Petworth Union, and the question which the jury had to decide before the coroner (Mr. Richard Blagden) was, whether she had not destroyed her illegitimate child by the administration of white precipitate.

It appears that the deceased had been ill for some time past; that Mr. Short, the medical officer, was called to see it; that he administered for its malady, and it eventually recovered. On the Sunday, Monday, and Tuesday before its death, which took place on the Thursday, it seemed quite well again. On the Thursday evening, however, a person named Reimnan, who had been seen by the accused, was observed to give her a small parcel, which she put behind her back, and this was proved to be white precipitate.

Dr. Taylor said he would first proceed with the examination of the jars. He found the viscera in a good state of preservation. The lining membrane was congested at the upper part, and covered with mucus and extra food. There was no inflammation or ulceration about these parts, and the windpipe was in a healthy condition. The stomach had been opened and retied. He again opened it, and found a thick curdy whitish brown substance of the consistency of stiff paste; there was about enough to fill a large table spoon, and upon this was a thin and dark coagulation of blood. He found pasty matter closely adhering to the coats of the stomach, and mixed with mucus. On removing it, the greater part of the lining membrane of the stomach appeared pale, and towards the spinal opening there was a small patch arising from congestion of the lungs. The duodenum was greatly inflamed, and he observed a bright red colour. Inflammation was in the mucous and lining membranes chiefly. The liver, kidneys, heart, and lungs presented no appearance of disease. There was nothing about any of these organs to account for death. He then examined the different parts chemically, beginning at the upper and going down to the lower end. He took the gullet, and found it to contain a small quantity of a mercurial compound, and with it some starchy matter, which might be bread or arrowroot. On examining the contents of the stomach he found a number of chalky particles, which readily subsided when mixed with water. They did not dissolve, and had the appearance of mineral matter. He examined these contents microscopically and chemically, and found the greater part consisted of starchy matter (like gruel), undigested food, and mucus. With these was an insoluble compound of mercury, which had all the powers of white precipitate. He next examined the coats of the stomach after scraping away all the contents, and he found a small quantity of mercury in them. In the phial he did not discover any of the white particles which he had found in the stomach. He then proceeded to examine the napkins which had been forwarded in the brown paper parcel. He cut away a small portion of one of them with the matter upon it, which was of a green colour. It was found to contain, among other things, mucus, bile, and starchy matter, and a comparatively large quantity of a mercurial compound—that was, more than he had found in the body. In another portion of the napkin, which was unstained, he found starchy matter, but no mercury. He examined one half of the heart; no mercury was present. He examined a fifth part of the liver, and found mercury in it; and he afterwards examined one of the kidneys and separated mercury from it. From his examination and analysis he had drawn up certain conclusions which might be embodied thus:—First, that a mercurial compound, which he believed to be white precipitate mixed with farinaceous and other matter, was found in the contents of the stomach of the deceased infant; secondly, that a mercurial compound also mixed with starchy matter and mucus, was found in the discharge in the napkin; thirdly, that a mercurial compound and starchy matter were found in the middle portion of the gullet, and in the lower portion of the small intestines, and that mercury without starch was found in the various parts of the small and large intestines, as well as in the liver and one of the kidneys; fourthly, that the appearances presented by the viscera were redness in the gullet, a patch of redness in the stomach, and great redness with injections in the upper part of the small intestines—less in the large intestines (the redness of an inflammatory nature being what was called acute inflammation)—it was seated in the mucous or lining membrane, and such as might have been produced either by the action of an irritant substance, or else by the result of disease, and, fifthly and lastly, the heart, lungs, liver, kidneys, and spleen presented no appearance of disease and no appearance to account for death.

Dr. Taylor was then cross-examined at great length by the Coroner and jury, and simplified his evidence by further explanation, from which it appeared that this was a most extraordinary case, from the fact of white precipitate having been so rarely administered internally. He knew of only one case, and that was at Chelmsford Assizes, twelve years ago, in which he was engaged. The patient had taken twenty-five grains, and recovered. The whole point was this—whether the system possessed sufficient strength to throw it off by vomiting.

The jury, after consulting for about an hour, returned a unanimous verdict of wilful murder.

ANSWERS TO CORRESPONDENTS.

C. P.—The processes are necessarily complicated. The best account we know is in the *Handbook of Chemistry*, by Abel and Bloxam.

S. J. had better advertise in the Chemical News. There are several gentlemen who give instruction.

W. G. (Oxford).—You are quite right in the first case. In the second the chloroform separates, and the mixture must be well shaken before a dose is measured.

F. W.—1, Gum-Arabic is insoluble in alcohol. 2, We cannot say.

R. J. S.—Equal weights of sal ammoniac, nitrate of potash, and common salt, and cold water equal to the weight of the mixed salts, form the best freezing mixture that we are acquainted with.

N. F.—We know of none available for our correspondent's purpose.

Amateur (Glasgow).—All the receipts are bad. The ink will inevitably destroy the paper. As space permits, we shall give the information desired.

A Reader.—The articles are not quoted in price currents. Ure's Dictionary will give the information.

A. B. (Bradford).—Uric acid can be obtained from urine: but the quantity is very small, and is very difficult to purify.

W. G. (Leeds).—Dr. Odling has a work in the press, nearly ready, which will fully explain the Unitary system of Chemical Notation.

Chemist.—The true Brunswick green is subchloride of copper.

A Sub. (Manchester).—We believe not.

Books and Journals received.—The Dublin Medical Press. The Practice of Hiring Wet Nurses, &c.

*** All *Editorial Communications* are to be addressed to the Editor; and *Advertisements* and *Business* communications to the Publisher, at the Office; 12 and 13 Red Lion Court, Fleet Street, London. E. C.

VOL. I. No. 8. — January 28, 1860.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On some Properties of the Platinum Metals, by MM. DEVILLE *and* DEBRAY.[1]

THE platinum metals have particular characters, which completely separate them from the more or less natural divisions, into which the other metals have been formed. It will be well, in our opinion, to make of them a single group, which shall contain them all and admit no others. It is true that these metals are not analogous in every respect; but they have a common physiognomy, and a peculiar character which will always oblige us to study them together, even if, with a view to a rational classification, they should be distributed among different families of the simple bodies.

These metals are never found apart from one another, except, and then but rarely, palladium; and palladium is, of all of them, the one most nearly allied to the other metals. More or less alterable under the influence of oxygen and chlorine, they are all allied by the facility with which they give up to reducing agents the elements with which they are combined. Their principal affinities are for the halogen bodies, such as chlorine, bromine, iodine and cyanogen; and with these bodies they all give birth to compounds characteristic of the series of platinum metals. Besides this they all have the curious property of determining a number of chemical reactions by their simple contact — their *catalytic action* as it has been called by Berzelius. This last action cannot be ascribed to the porosity of the metals, for platinum which has been melted and worked with the hammer is as active in this respect as platinum which has been obtained by the aggregation of its powder.

The differences between these bodies are equally remarkable. Thus osmium which burns in the air and gives rise to vapours of osmic acid, has been compared by Berzelius to arsenic; later, M. Dumas inclines to range it by the side of tellurium: but most assuredly it is a metalloid, the metalloid of the platinum series. Ruthenium is allied to tin by its chemical properties and the form of its oxide. Palladium resembles silver in its volatility, its oxidability, and its action upon hydriodic acid, &c.; but the strong basic property of oxide of silver is not met with in any of the oxides of palladium. Rhodium cannot be compared with any other metal. It resembles silver in its oxidability by heat, in the basic properties of its principal oxide, and in the remarkable action which it exerts upon sulphuric acid or rather the bisulphate of potash; and is like gold in the reactions of its chlorides. Platinum is in all its properties a true analogue of gold. Iridium presents few analogies with the ordinary metals, being superior to all of them in its resistance to the action of our most powerful reagents; and if its physical properties were in accordance with its chemical, iridium rather than gold would be the king of metals.

[1] Abridged from the *Annales de Chimie et de Physique*.

We now proceed to give in detail the author's account of the metals.

1. **Osmium.** — Until now osmium has been prepared in such a state that the history of its physical properties is as incomplete as that of iron would be if we only knew it in the pyrophoric condition, or as silicium or boron, if they were only known as amorphous matters eminently combustible. We have considered osmium as a metalloid; and in fact, like a certain number of metalloids, osmium has the power of entirely changing its chemical and physical properties according to the manner in which it is prepared. Ordinary osmium, prepared according to the process of Berzelius, is a spongy, half metallic mass, which gives off an odour of osmic acid, indicating a sensible alteration by oxygen at the ordinary temperature. It density is equal to 7. If however it is obtained by reducing the vapour of osmic acid with hydrogen, it is metallic and has a density of about 10.

Pulverulent Osmium. — But osmium appears with altogether different characters when prepared in the following manner. We take osmide of iridium in fine powder — if we have none naturally pulverulent we reduce the scales to powder chemically, by calcining them with 4 or 5 times their weight of zinc. When all trace of the zinc has disappeared from the flame we allow the crucible to cool, and there is found a porous friable mass weighing exactly as much as the osmide introduced. One part of this is mixed with 5½ times its weight of binoxide of barium, and the mixture is heated for an hour or two in a well covered crucible to the temperature of melted silver. After this a black homogeneous mass is found which we break up and place in a glass retort; a little water is then added and afterwards 8 parts of hydrochloric and 1 part of nitric acid. These are shaken together and distilled, taking care to keep the receiver well cooled to avoid the escape of the osmic vapours. When the vapour no longer has the smell of osmic acid, the distillation is stopped, and the liquid in the receiver is distilled afresh, and the product is condensed in diluted ammonia.

The osmiate of ammonia is supersaturated with sulphuretted hydrogen, and the liquor containing the sulphide of osmium is boiled for some time and then filtered.

The sulphide of osmium, dried at a low heat, is placed in a crucible of coke, which is itself enclosed in another crucible of refractory clay and then heated for 4 or 5 hours to the temperature of melted nickel. The sulphide is reduced by the heat and there is left a brilliant metal of a blue colour brighter than that of zinc. If the heat is raised to that of melted rhodium we have a metal whose density is equal to 21·3 or 21·4. This osmium is without smell and only becomes combustible at a temperature higher than that of melted zinc.

Crystallised Osmium. — When osmium is heated to bright redness with 7 or 8 times its weight of tin in a charcoal crucible, and the melted mass is allowed to cool slowly, the osmium separates in a crystalline form. It is

only necessary to dissolve out the tin with hydrochloric acid, to obtain the crystals of osmium in a state of purity. The crystals are too small to be measured: they are probably rhomboidal dodecahedra with cubic faces.

Compact Osmium.—When osmium is dissolved in zinc, and the zinc afterwards separated by hydrochloric acid, osmium is obtained as a very combustible amorphous powder; but when the zinc is volatilised, and the residue is submitted to the heat of the gas furnace (the apparatus was described in No. 1 of the CHEMICAL NEWS) the osmium is found completely metallic with the brightness and blue colour characteristic of the metal: it is not melted but is full of irregular cavities. This osmium scratches glass easily. We have tried in vain to fuse it at a temperature which we estimate to correspond with that of melted rhodium.

After this treatment osmium has a metallic lustre and a light blue colour. Its density=21·4. It presents no appearance of a fusion; and as no smell of osmium was perceived during the operation, we may say that in closed vessels, at the temperature at which rhodium fuses, osmium is infusible and fixed. It is not so at the heat of melted iridium, for when this temperature is attained considerable quantities of osmium disappear, and are deposited on any cold body interposed near the flame. We conclude from these experiments that at the temperature at which iridium is in complete fusion, and platinum itself is vaporised, osmium becomes volatile, but even the practised eye which follows the operation can discover no trace of fusion.

MM. Thenard and Dulong discovered that osmium like platinum has the power of effecting the combination of bodies by simple contact with the reacting substances. Our experiments have confirmed this not only with regard to osmium but with all the metals of the platinum series, in which it exists to a remarkable degree.

Osmic Acid.—Osmic acid is prepared dry by roasting according to the process of M. Fremy, which sometimes succeeds well and sometimes badly according to the nature of the osmides. When they are not easily roasted we mix them with 8 or 10 times the weight of zinc and digest at a red heat for some hours, and then treat the alloy with hydrochloric acid, which leaves a powder so combustible that osmic acid is disengaged at the ordinary temperature, and which takes fire at 400° C.

As osmic acid boils at about 100° C. it is easy to take the density of the vapour. The first determination at the temperature of 246° C. gave 8·99; the second at 286° C. gave 8·88. The density is calculated at 9.

Ruthenium.—After osmium, ruthenium is the most refractory metal we are acquainted with. It requires a very extreme heat to melt the smallest quantity. When melting there is formed the oxide of ruthenium (RuO_2) which is volatilised, and which smells something like osmic acid. When removed from the flame ruthenium is blackish-brown on the surface and is brittle and hard like iridium. It is only distinctly separated from this last metal by its density, which is obviously half that of iridium. The purest ruthenium we could obtain weighed from 11 to 11·4; it had been fused a great number of times in nitre and potasse, in which iridium becomes insoluble when the ruthenium is in great excess.

To prepare the metal we mix the osmide in fine powder with 3 parts of binoxide of barium and 1 part of nitrate of baryta and heat them to redness in a clay crucible for an hour. The black friable mass which remains is powdered with great care and introduced into a flask in which has been previously mixed 20 parts of water and 10 parts of ordinary muriatic acid. The flask must be placed in cold water to avoid the elevation of temperature which would ensue from the violent reaction which takes place. This operation should be conducted under a good chimney to avoid the escape of the osmic acid vapour into the laboratory.

When this reaction is finished 1 part nitric acid is added, and then 2 parts ordinary strong sulphuric acid. The flask is now well shaken, and the sulphate of baryta is allowed to deposit. The supernatant liquid is then poured off, the precipitate is washed by decantation, and the liquid and the washings are distilled together in a tubulated retort, until about a fourth of their volume of a liquid very rich in osmic acid has passed over. The red liquor which is left in the retort is evaporated to a small volume, 2 or 3 parts of sal ammoniac in small pieces are added, and a small quantity of nitric acid. The whole is now evaporated to dryness at the temperature of boiling water. A crystalline violet-black precipitate remains in the capsule, which we treat with a small quantity of water partly saturated with sal ammoniac, and wash with the same solution until it is no longer coloured. The insoluble salt left (chloro-iridiate of ammonia containing ruthenium) is heated by degrees to redness in a porcelain crucible. The mixture of iridium and ruthenium thus obtained is fused in a silver crucible with an equal weight of hydrated potash and twice its weight of nitre, and when cold the ruthenate of potash is dissolved out with cold water: the solution, which is yellow, is decomposed by means of carbonic or nitric acid, and the precipitated oxide of ruthenium is strongly calcined in a charcoal crucible. The ruthenium is then reduced in the apparatus before described. Iridium and ruthenium present many analogies; their coloured reactions are the same, and the oxide of iridium dissolves in a mixture of nitre and potash.

Ruthenium forms with zinc an alloy which will burn in the air; it crystallises in hexagonal prisms. With tin there is formed an alloy $RuSn_2$, which crystallises in cubes as beautiful in their form and lustre as crystallised bismuth.

Palladium.—This is the most fusible of all the platinum metals. The gas furnaces (page 6, CHEMICAL NEWS) easily bring it into a liquid state, and when heated to the temperature of fused iridium it disappears, giving off green vapours, which condense into a bistre-coloured dust, being a mixture of the metal and its oxide. Heated in contact with the air, and maintained in a state of fusion in an oxidising atmosphere, it *spits* like silver at the moment of solidification; but the exterior of the button is smooth, while the interior is cavernous. It is more oxidisable than silver, for it tarnishes in the air. The density of pure palladium, melted but not hammered, is 11·4 at the temperature 72° Fahr.

Palladium is soluble in zinc, but does not combine with it. By fusion with tin, however, it forms an alloy which crystallises in brilliant laminæ, having the composition Pd_2Sn_3. Silver and copper, which have a great analogy to palladium, give alloys with tin, exactly resembling the foregoing in form and composition.

Rhodium.—Rhodium is obtained by fusing platinum residues with an equal weight of lead and twice its weight of litharge. When the crucible has attained a bright red heat, and the litharge is thoroughly liquid, the crucible is shaken once or twice, and is then allowed to cool slowly. The button of lead, which contains all the metals in the residue less oxidisable than lead, is treated with nitric acid diluted with an equal volume of water, which removes besides the lead the copper and

the palladium. The insoluble powder which remains is mixed with five times its weight of binoxide of barium, weighed exactly, and is heated to redness in a clay crucible for one or two hours. After this it is first treated with water, and then with aqua regia to remove the osmic acid. When the liquor has lost all smell, sufficient sulphuric acid is added to exactly precipitate the baryta. It is then boiled, filtered, and evaporated, first adding to it a little nitric acid and then a great excess of sal ammoniac. The evaporation is carried to dryness at 212°, and the residuum is washed with a concentrated solution of sal ammoniac which removes all the rhodium. When the washings are no longer coloured, the liquor is evaporated with a great excess of nitric acid, which destroys the sal ammoniac, and when only the salt of rhodium is left, the evaporation is finished in a porcelain crucible. The rhodium salt is now moistened with hydrosulphuret of ammonia, mixed with three or four times its weight of sulphur, and the crucible is heated to bright redness, after which metallic rhodium is left in the crucible. So obtained rhodium may be considered almost pure, after it has been boiled for some time first in aqua regia, and then in concentrated sulphuric acid. To obtain it perfectly pure it must be melted with four times its weight of zinc. The alloy is treated with concentrated hydrochloric acid which dissolves most of the zinc but leaves a crystalline matter which is really an alloy of rhodium and zinc in definite proportions. This is dissolved in aqua regia, and the solution is treated with ammonia until the precipitate first formed is redissolved. The solution is boiled and evaporated, by which is obtained the yellow salt, or chloride of rhodium. This is purified by repeated crystallisation, and then calcined with a little sulphur, by which means rhodium is procured absolutely pure.

Rhodium melts less easily than platinum, so much so that the same fire which will liquefy 300 grammes of platinum will only melt 40 or 50 grammes of rhodium. It is not volatilised, but it oxidises on the surface like palladium. Less white and lustrous than silver it has about the same appearance as aluminium. When perfectly pure it is ductile and malleable, at least after fusion. Its density is 12·1.

The alloys of rhodium, those at least which have been examined, are true chemical combinations, as is shown by the high temperature developed at the moment of their formation. The alloy with zinc already described resists the action of muriatic acid, but in contact with *air* and the *acid* there is soon a well marked rose coloration which reveals an oxidation of the two metals under the double influence of the air and acid. The alloy with tin is crystallised, black, brilliant and fusible at a very high temperature.

Iridium.—The chloro-iridiate of ammonia containing ruthenium obtained in the preparation of the latter metal is dried and calcined, whereby a powder is obtained from which we remove the last traces of chlorine and oxygen by means of a current of hydrogen. Platinum and a little of the osmium are extracted by aqua regia and the ruthenium is separated by fusion with nitre and potassa, followed by prolonged washing with water. The osmium which remains is removed by placing the metal in the oxidising flame of the blowpipe; and the metal is then melted in the lime furnace, using, however, pure hydrogen in the place of coal gas. The colour of iridium is pure white, somewhat resembling polished steel. It breaks under the hammer at the ordinary temperature of the air; but it becomes malleable when it is raised to a bright white heat.

PHARMACY, TOXICOLOGY, &c.

On some Specimens of Dugong Oil, by W. T. Fewtrell.

A few years ago Dr. Hobbs, the health officer at Moreton Bay introduced the oil obtained from the dugong as a substitute for cod-liver oil. This animal is one of the herbivorous cetacea, and is found on the northern coast of Australia, in the Red Sea, the Persian Gulf, and also in the Indian seas. *Dugong*, *dou-joung*, or *duyong*, is a Malay word, which signifies sea-cow. The Dutch in the Indian archipelago called it *zee-koe;* among the Spaniards it was known as the *peixe dono*, or sea-woman; and French naturalists have given it the name of *halicore*, sea-girl or syren. The Red Sea variety has been named by Ruppel the *Halicore tabernaculus*, in consequence of historical researches having led him to the conclusion that it was with the skin of this animal that the Jews were ordered to veil the tabernacle. In the Indian seas it is sometimes found of large size, from 18 to 20 feet long; but in Australia it is seldom found longer than 12 or 14 feet. The following description of the animal is borrowed from the *Naturalists' Library* and other works. In its general form the dugong resembles the common whale. The skin is smooth and thick, bluish above and white beneath, with a few remote and scattered hairs; the mammæ are situated on the chest, under the fins. The head is small in proportion and of a peculiar form. The upper lip is very large, thick, and obliquely truncated, forming a short, thick, and nearly vertical kind of snout, something like the trunk of an elephant cut short across. The surface of the truncated portion is covered with soft papillæ, and furnished with a few bristles; the lips are covered with a horny substance which assists in tearing the sea-weeds for food. The lower lip is much smaller, and resembles a round or oblong chin. To assist the animals in browsing upon the submarine vegetables, the anterior portion of the jaw is bent downwards at an angle, in such a way as to bring the mouth into a nearly vertical position. The greatest peculiarity of the animal is that the ventricles of the heart are widely detached from each other, being connected at the base only. Another singular circumstance is that the *inside* of the cheeks are studded with strong projecting bristles. The pectoral fins resembling swimming paws, have no nails, but are verrucose. The tail is broad, horizontal, and crescent-shaped.

"Its favourite haunts are the mouths of rivers and straits between proximate islands, where the depth of water is but trifling (three or four fathoms), and where, at the bottom, grows a luxuriant pasturage of submarine algæ and fuci. Here, in calm weather, may small troops be seen feeding below the surface, and every now and then rising to take breath. The position of the mouth, the muscular powers, and mobility of the lips, garnished with wiry bristles, and the short incisor tusks of the upper jaw, enable these animals to seize and drag up the long fronds of sub-aquatic vegetables, which constitute their nourishment. The mutual affection of the male and female is very great, and the latter is devoted to her offspring. If a dugong be killed, the survivor of the pair, careless of danger, follows after the boat carrying the body, impelled by an overmastering passion, and thus often shares the fate of its partner; indeed if one be taken, the other is an easy prize."

It is taken by Malays and also by the aborigines of Moreton Bay for the sake of its flesh, which is said to be very delicate and palatable, and to resemble young beef. The natives of Australia also used the oil for

burning. Mr. Archer, who was at Moreton Bay before the oil was used as a medicine, tells me that the natives waited until a shoal got into a shallow water, and then surrounded and drove them into large nets. The oil was obtained by skinning the fish and then boiling down the "speck." Not much was obtained, the annual produce being estimated at about 200 gallons. Mr. Archer adds that when opened the stomach of the animal was always found full of sea-weeds and *live worms*.

Now that a large demand for the oil has sprung up, a fishery has been organised, and the dugong has been taken in great numbers, but still not sufficient to supply the amount of oil in requisition; and the deficiency would appear to be made up from an altogether different source.

But small quantities of what is called dugong oil have arrived in England, and I have only had the opportunity of examining three specimens. One was kindly given to me by Dr. Letheby, who received it some years ago before the oil was in repute. Another, also given to me by Dr. Letheby, was, I believe, received at the Consumption Hospital a few months ago. The third was imported expressly for me by Messrs. Johnson and Archer, Australian merchants. The price paid in Australia for a bottle containing about a pound and a quarter was 12*s.* 6*d.* All these specimens are solid at the ordinary temperature of the air, but with the first (which is of a brown colour) there is a small quantity of dark coloured oil on the surface. The others are white and perfectly solid. Considering the supposed source of the oil, it would be imagined that the dugong oil would present the same appearances, have the same smell and behave in the same way with chemical tests as the oils obtained from other cetaceans. Such, however, is not the case with the specimens I have examined, except, and then but partially, with the first. Of the smell of the first it is impossible to speak, for it has become so rancid that the natural smell of the fresh oil must be entirely gone. The other two when cold have a faint odour of tallow, which is greatly heightened when the oil is made hot. Strong sulphuric acid dropt on the first produces a deep brown colour—on the other two, only a pale yellow colour. Chlorine gas passed through the first deepened the original brown colour, but the other two were unaffected by it. Now, remembering the action of these reagents on the oil from other cetaceans, I am inclined to think that neither of these three samples is genuine. I speak with diffidence in the absence of a well authenticated specimen to use as a standard of comparison; but I believe that two out of the three are entirely factitious (mixtures probably of a vegetable oil with some solid animal fat), and that the other is largely adulterated. I am confirmed in this opinion by the following statement made by Dr. Hobbs in the *Melbourne Argus*:—"During a given period, when there was being sold in Sydney 50 gallons weekly, and in Melbourne 100 gallons weekly, there was little more than 100 gallons got from the Bay."

Under these circumstances, I would recommend an importer to receive with caution any consignment of the so-called dugong oil. It does not seem to possess any decided advantage over cod-liver oil, and its principal recommendation in Australia is that it is a colonial production. The very high price will prevent the export of much to England; and in a few years the supply will most likely cease. Several years ago a Frenchman wrote: "Tout annonce que dans quelques années le dugong aura entièrement disparu de dessus le globe;" and it is likely that the prophecy will be speedily accomplished as far as Australia is concerned.

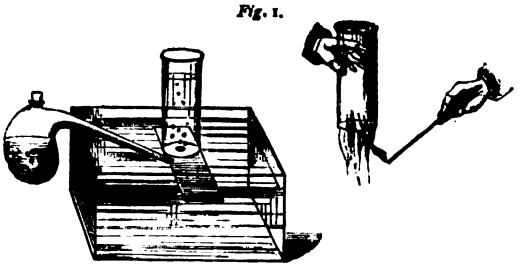
ROYAL INSTITUTION OF GREAT BRITAIN.

A Course of Six Lectures[1] *(adapted to a Juvenile Auditory), consisting of Illustrations of the Various Forces of Matter, i. e. of such as are called the Physical or Inorganic Forces—including an Account of their Relations to each other; by* M. Faraday, *D.C.L., F.R.S., Fullerian Professor of Chemistry, R.I., Foreign Associate of the Academy of Sciences, Paris, &c.*

Lecture IV. (Jan. 5, 1860.) *Chemical Affinity—Heat.*

We shall have to pay a little more attention to the forces existing in water before we can have a clear idea on the subject. Besides the attraction which there is between its particles to make it hold together as a liquid or a solid, there is also another force, different from the former;—one which by means of the voltaic battery we yesterday overcame, drawing from the water two different substances, which when heated by means of the electric spark attracted each other, and rushed into combination to reproduce water. Now the best thing I can do to day is to continue this subject, and trace the various phenomena of chemical affinity; and for this purpose, as we yesterday considered the character of oxygen, of which I have here two jars (oxygen being those particles derived from the water which enable other bodies to burn), we will now consider the other constituent of water, and without embarrassing you too much with the way in which these things are made, I will proceed now to show you our common way of making *hydrogen*. (I called it hydrogen yesterday—it is so called because it helps to generate water.)[2] I put into this retort some zinc, water, and oil of vitriol, and immediately an action takes place, which produces an abundant evolution of gas now coming over into this jar, and bubbling up in appearance exactly like the oxygen we obtained yesterday.

Fig. 1.



The processes you see are very different, though the result is the same in so far as it gives us certain gaseous particles. Here then is the hydrogen; I showed you yesterday certain qualities of this gas, now let me show you some other qualities. It is a combustible substance, not like the oxygen, which is a supporter of combustion, although it will not burn. There is a jar full of it, and if I carry it along in this manner, and put a light to it, I think you will see it take fire, not with a bright light,—you will at all events hear it if you do not see it. Now that is a body entirely different from oxygen; it is extremely light; for although you yesterday saw twice as much of this hydrogen produced on the one side as the other, by the voltaic battery, it was only one eighth the weight of the oxygen. I carry this jar upside down. Why? Because I know that it is a very light body, and that it will continue in this jar upside down quite as effectually as the water will in that jar which is not upside down; and just as I can pour water from one vessel into another in the right position to receive it, so can I pour this gas from one jar into another when they are upside down. See what I am about to do,—there is no hydrogen in this jar at present, but I will gently turn this jar of hydrogen up under this other jar (*fig.* 2.) and then we will examine the two. We shall see, on applying a light, that the hydrogen has left the jar in which it was at first, and has poured upwards into the other, and there we shall find it.

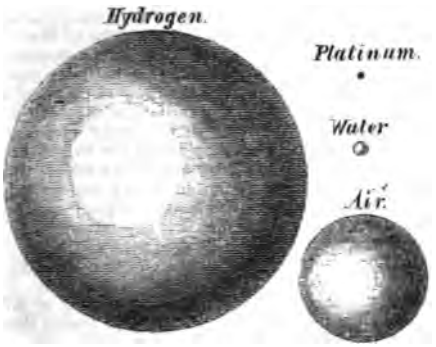
Fig. 2.

You now understand that we can have particles of very diffe-

[1] Reported verbatim by special permission.
[2] ὕδωρ, "water," and γείνομαι, "I generate."

rent kinds, and that they can have different bulks and weights; and there are two or three very interesting experiments which serve to illustrate this. For instance, if I blow soap bubbles with the breath from my mouth you will see them fall, because I fill them with common air, and the water which forms the bubble carries it down. But now if I inhale hydrogen gas into my lungs (it does no harm to the lungs, although it does no good to them), see what happens. [The Lecturer inhaled some hydrogen, and after one or two ineffectual attempts, succeeded in blowing a splendid bubble, which rose majestically and slowly to the ceiling of the theatre, where it burst.] That shows you very well how light a substance this is; for notwithstanding all the heavy bad air from my lungs, and the weight of the bubble, you saw how it was carried up. I want you now to consider this phenomenon of weight as indicating how exceedingly different particles are one from the other: and I will take as illustrations these very common things, air, water, the heaviest body—platinum—and this gas, and observe how they differ in this respect; for if I take a piece of platinum of that size (*fig.* 3.) it is equal to the weight of portions of water, air, and hydrogen of the bulks I have represented in

Fig. 3.



these spheres; and this illustration gives you a very good idea of the extraordinary difference with regard to the gravity of the articles having this enormous difference in bulk. [The following tabular statement having reference to this illustration appeared on the diagram board.]

Hydrogen	1		
Air	14·4	1	
Water	11943	829	1
Platinum	256774	17831	21·5

Whenever oxygen and hydrogen unite together they produce water, and you have seen the extraordinary difference between the bulk and appearance of the water so produced and the particles of which it consists chemically. Now we have never yet been able to reduce either oxygen or hydrogen to the liquid state; and yet their first impulse when chemically combined is to take up first this liquid condition and then the solid condition. We never combine these different particles together without producing water; and it is curious to think how often you must have made the experiment of combining oxygen and hydrogen to form water without knowing it. Take a candle, for instance, and a clean silver spoon (or a piece of clean tin will do), and if you hold it over the flame you immediately cover it with a dew—not a smoke—which presently evaporates. This perhaps will serve to show it better. Mr. Anderson will put a candle under that jar, and you will see how soon the water is produced (*fig.* 4.). Look at that dimness on the sides of the glass, which will soon produce drops and trickle down into the plate Well, that dimness and these drops are *water*, formed by the union of the oxygen of the air with the hydrogen existing in the wax of which that candle is formed.

Fig. 4.

And now, having brought you in the first place to the consideration of chemical attraction, I must enlarge your ideas so as to include all substances which have this attraction for each other—for it changes the character of bodies, and alters them in this way and that way, in the most extraordinary manner; and produces other phenomena wonderful to think about. Here is some chlorate of potash, and there is some sulphuret of antimony. We will mix these two different sets of particles together, and I want to show you in a general sort of way, some of the phenomena which take place when we make different particles act together. Now I can make these bodies act upon each other in several ways. In this case I am going to apply heat to the mixture, but if I were to give it a blow with a hammer the same result would follow. [A lighted match was brought to the mixture, which immediately exploded with a sudden flash, evolving a dense white smoke.] There you see the result of the action of chemical affinity, overcoming the attraction of cohesion of the particles. Again, here is a little sugar, quite a different substance from the black sulphuret of antimony, and you shall see what takes place when we put the two together. [The mixture was touched with sulphuric acid, when it took fire and burnt gradually and with a brighter flame than in the former instance.] Observe this chemical affinity! travelling about the mass, and setting it on fire, and throwing it into such wonderful agitation.

I must now come to a few circumstances which require careful consideration. We have already examined one of the effects of this chemical affinity—but to make the matter more clear we must point out some others. And here are two salts dissolved in water. They are both colourless solutions, and in these glasses you cannot see any difference between them. But if I mix them, I shall have chemical attraction take place. I will pour the two together into this glass, and you will at once see, I have no doubt, a certain amount of change. Look, they are already becoming milky, but they are sluggish in their action—not quick as the others were—for we have endless varieties of rapidity in chemical action. Now if I mix them together, and stir them so as to bring them properly together, you will soon see what a different result is produced. As I mix them they get thicker and thicker, and you see the liquid is hardening and stiffening, and before long I shall have it quite hard; and before the end of the lecture, it will be a solid stone—a wet stone no doubt, but more or less solid—in consequence of the chemical affinity. Is not this changing two liquids into a solid body a wonderful manifestation of chemical affinity?

There is another remarkable circumstance in chemical affinity, which is that it is capable of either waiting or acting at once. And this is very singular, because we know of nothing of the kind in the forces either of gravitation or cohesion. For instance, here are some oxygen particles, and here is a lump of carbon particles. I am going to put the carbon particles into the oxygen; they *can* act, but they *do* not—they are just like this unlighted candle. It stands here quietly on the table, waiting until we want to light it. But it is not so in this other case: here is a substance, gaseous like the oxygen, and if I put these particles of metal into it the two combine at once. The copper and the chlorine unite by their power of chemical affinity, and produce a body entirely unlike either of the substances used. And in this other case, it is not that there is any deficiency of affinity between the carbon and oxygen, for the moment I choose to put them in a condition to exert their affinity, you will see the difference. [The piece of charcoal was ignited, and introduced into the jar of oxygen, when the combustion proceeded with vivid scintillations.]

Now this chemical action is set going exactly as it would be if I had lighted the candle, or as it is when the servant puts coals on and lights the fire: the substances wait until we do something which is able to start the action. Can anything be more beautiful than this combustion of charcoal in oxygen? You must understand that each of these little sparks is a portion of the charcoal, or the bark of the charcoal, thrown off white-hot into the oxygen, and burning in it most brilliantly as you see. And now let me tell you another thing, or you will go away with a very imperfect notion of the powers and effects of this affinity. There you see some charcoal burning in oxygen. Well, a piece of lead will burn in oxygen just as well as the charcoal does, or indeed better, for absolutely that piece of lead will act at once upon the oxygen as the copper did in the other vessel with regard to the chlorine. And here also is a piece of iron; if I light it and put it into the oxygen, it will burn away just as the carbon did. And I will take some lead and show you that it will burn in the common atmospheric oxygen at the ordinary t[illegible] These are the lumps of lead which you remember

other day — the two pieces which clung together. Now these pieces, if I take them to day and press them together, will not stick, and the reason is that they have attracted from the atmosphere a part of the oxygen there present, and have become coated as with a varnish by the oxide of lead which is formed on the surface, by a real process of combustion or combination. There you see the iron burning very well in oxygen, and I will tell you the reason why those scissors and that lead do not take fire whilst they are lying on the table. Here the lead is in a lump, and the coating of oxide remains on its surface, whilst there you see the melted oxide is clearing itself off from the iron, and allowing more and more to go on burning. In this case, however [holding up a small glass tube containing lead pyrophorus], the lead has been very carefully produced in fine powder, and put into a glass tube and hermetically sealed so as to preserve it, and I expect you will see it take fire at once. This has been made about a month ago, and has thus had time enough to sink down to its normal temperature — what you see therefore is the result of chemical affinity alone. [The tube was broken at the end, and the lead poured out on to a piece of paper, whereupon it immediately took fire.] Look, look, at the lead burning; why it has set fire to the paper. Now that is nothing more than the common affinity always existing between very clean lead and the atmospheric oxygen; and the reason why this iron does not burn until it is made red-hot, is because it has got a coating of oxide about it which stops the action of the oxygen,—putting a varnish, as it were, upon its surface, as we varnish a picture—absolutely forming a substance which prevents the natural chemical affinity between the bodies from acting.

I must now take you a little further in this kind of illustration, or consideration I would rather call it, of chemical affinity. This attraction between different particles exists also most curiously in cases where they are previously combined with other substances. Here is a little chlorate of potash containing the oxygen which we found yesterday could be procured from it; it contains the oxygen there combined and held down by its chemical affinity with other things; but still it can combine with sugar, as you saw. This affinity can thus act *across* substances, and I want you to see how curiously what we call combustion acts with respect to this force of chemical affinity. Suppose I take a piece of phosphorus and set fire to it, and then place a jar of air over the phophorus, you see the combustion which we are having there on account of chemical affinity (combustion being in all cases the result of chemical affinity). The phosphorus is escaping in that vapour, which will condense into a snow-like mass at the close of the lecture. But suppose I limit the atmosphere, what then? why, even the phosphorus will go out. Here is a piece of camphor which will burn very well in the atmosphere, and even on water it will float about and burn, by reason of some of its particles gaining access to the air. But if I limit the quantity of air by placing a jar over it, as I am now doing, you will soon find the camphor will go out. Well, why does it go out? not for want of air, for there is plenty of air remaining in the jar. Perhaps you will be shrewd enough to say for want of oxygen.

This therefore leads us to the inquiry as to whether oxygen can do more than a certain amount of work. The oxygen there (*fig.* 4.) cannot go on burning an unlimited quantity of candle, for that has gone out, as you see; and its amount of chemical attraction or affinity is just as strikingly limited; it can no more be fallen short of or exceeded than can the attraction of gravitation. You might as soon attempt to destroy gravitation, or weight, or all things that exist, as to destroy the exact amount of force exerted by this oxygen. And when I pointed out to you that 8 by weight of oxygen to 1 by weight of hydrogen went to form water, I meant this, that neither of them would combine in different proportions with the other, for you cannot get 10 of hydrogen to combine with 6 of oxygen, or 10 of oxygen to combine with 6 of hydrogen — it must be 8 of oxygen and 1 of hydrogen. Now suppose I limit the action in this way; this piece of cotton-wool burns, as you see, very well in the atmosphere; and I have known of cases of cotton-mills being fired as if with gunpowder, through the very finely divided particles of cotton being diffused through the atmosphere in the mill, when it has sometimes happened that a flame has caught these raised particles, and it has run from one end of the mill to the other and blown it up. That then is on account of the affinity which the cotton has for the oxygen; but suppose I set fire to this piece of cotton which is rolled up tightly; it does not go on burning, because I have limited the supply of oxygen, and the inside is prevented from having access to the oxygen, just as it was in the case of the lead by the oxide. But here is some cotton which has been imbued with oxygen in a certain manner. I need not trouble you now with the way it is prepared; it is called gun-cotton. See how that burns [setting fire to a piece]; it is very different from the other, because the oxygen that must be present in its proper amount is put there beforehand. And I have here some pieces of paper which are prepared like the gun-cotton, and imbued with bodies containing oxygen. Here is some which has been soaked in nitrate of strontia — you will see the beautiful red colour of its flame; and here is another which I think contains baryta, which gives that fine green light; and I have here some more which has been soaked in nitrate of copper,—it does not burn quite so brightly, but still very beautifully. In all these cases the combustion goes on independent of the oxygen of the atmosphere. And here we have some gunpowder put into a case, in order to show that it is capable of burning under water. You know that we put it into a gun, shutting off the atmosphere, with shot, and yet the oxygen which it contains supplies the particles with that without which chemical action could not proceed. Now I have a vessel of water here, and am going to make the experiment of putting this fuse under the water, and you will see whether that water can extinguish it; here it is burning out of the water, and there it is burning under the water, and so it will continue until exhausted, and all by reason of the requisite amount of oxygen being contained within the substance. It is by this kind of attraction of the different particles one to the other that we are enabled to trace the laws of chemical affinity, and the wonderful variety of the exertions of these laws.

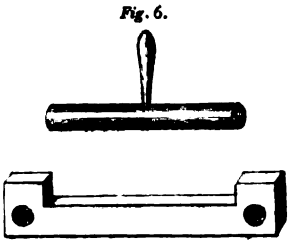
Now I want you to observe that one great exertion of this power which is known as *chemical affinity* is to produce HEAT and light; you know as a matter of fact, no doubt, that when bodies burn they give out heat, but it is a curious thing that this heat does not continue—the heat goes away as soon as the action stops, and you see by that that it depends upon the action *during the time* it is going on. That is not so with gravitation; this force is continuous, and is just as effective in making that lead press on the table as it was when it first fell there. Nothing occurs there which disappears when the action of falling is over; the pressure is upon the table, and will remain there until the lead is removed; whereas, in the action of chemical affinity to give light and heat, they go away immediately the action is over. This lamp *seems* to evolve heat and light continuously, but it is owing to a constant stream of air coming into it on all sides, and this work of producing light and heat by chemical affinity will subside as soon as the stream of air is interrupted. What then is this curious condition of heat? Why it is the evolution of another power of matter, of a power new to us, and which we must now consider as if were the very first time it was brought under our notice. What is heat? We recognise heat by its power of liquefying solid bodies and vapourising liquid bodies, by its power of setting chemical affinity going and very often overcoming it. Then how do we obtain heat? We obtain it in various ways; most abundantly by means of the chemical affinity we have just before been speaking about, but we can also obtain it in many other ways. Friction will produce heat. The Indians rub pieces of wood together until they get them hot enough to take fire, and such things have been known as two branches of a tree rubbing together so hard as to set the tree on fire. I do not suppose I shall set these two pieces of wood on fire by friction; but I can readily produce heat enough to ignite some phosphorus. [The Lecturer here rubbed two pieces of cedar wood strongly against each other for a minute, and then placed on them a piece of phosphorus, which immediately took fire.] And if you take a smooth metal button stuck on a cork, and rub it on a piece of soft deal wood, you will make it so hot as to scorch wood and paper, and burn a match.

Fig. 5.

I am now going to show you that we can obtain heat not by chemical affinity alone, but by the pressure of air. Suppose I take a pellet of cotton and moisten it with a little ether, and put it into a glass tube (*fig.* 5.), and then take a piston and press it down suddenly, I expect I shall be able to burn a little of that ether in the vessel. It wants a suddenness of pressure, or we shall not do what we require. [The piston was forcibly pressed down, when a flame due to the combustion of the ether was visible in the lower part of the syringe.] All we want is to get a little ether in vapour, and give fresh air each time, and so we may go on again and again getting heat enough by the compression of air to fire the vapour of ether.

This then, I think, will be enough, accompanied with all you have previously seen, to show you how we procure heat. And now for the effects of this power. We need not consider many of them on the present occasion, because when you have seen its power of changing ice into water and water into steam, you have seen the two principal results of the application of heat. I want you now to see how it expands all bodies—all bodies but one, and that under limited circumstances. Mr. Anderson will hold a lamp under that retort, and you will see the moment he does so that the air will issue abundantly from the neck which is under water, because the heat which he applies to the air causes it to expand. And here is a brass rod (*fig.* 6.) which goes through that hole and also fits accurately into this gauge; but if I make it warm with this spirit-lamp it will only go in the gauge or through the hole with difficulty; and if I were to put it into boiling water it would not go through at all. Again; as soon as the heat leaves bodies they collapse; see how the air is contracting in the vessel now Mr. Anderson has taken away his lamp: the stem of it is filling with water. And notice now that although I cannot get the tube through this hole or into the gauge, the moment I cool it by dipping it into water, it goes through with perfect facility, so that you see we have a perfect proof of this power of heat to contract and expand bodies.

Fig. 6.



(*The fifth Lecture, on* Magnetism *and* Electricity, *will be given in our next.*)

PROCEEDINGS OF SOCIETIES.

SOCIETY OF ARTS, *Wednesday, Jan.* 18.

Dr. Angus Smith read a paper at the Society of Arts entitled *Science in our Courts of Law*. The communication was very long, but we will endeavour to give our readers some idea of Dr. Smith's views. The doctor thinks that while the position of science is universally recognised, the position of the scientific man is not. He has no status in a court of law, but is allowed to appear under the vague name of a witness; and as such is liable to be cross-examined by an advocate, who is anxious to turn the evidence to the advantage of his client — a course which does not always tend to the elicitation of truth. But it is not right that the scientific man should act as advocate. He ought to be a student of nature, who loves whatever nature says in the most disinterested manner. If he becomes an advocate he is removed from his sphere, and the very ideal of his character is destroyed. Nor is he exactly fitted to be a judge. There is no trial in a court purely scientific. Individual and social rights are always involved, and it does not belong to a "scientist's" province to see the social bearings of a case. He is equally unfitted to act in the capacity of judge and jury united. All law has a tendency to pedantry, that is, a belief in its absolute perfection forgetful of numerous antagonistic possibilities for which a wider observation willingly makes allowance. The jury represents this wider observation of the untrammelled human spirit; and the number is twelve or more instead of one, because the operations of the individual spirit are uncertain; of the average man nearly certain. It represents also the absence of pedantry or the exaggeration of the law, by the absence of legal knowledge. If we put scientific inquirers in their place we increase the pedantry by adding physical to social law. Besides this it is against the principles of the country to give any class of men uncontrolled authority. Nor is Dr. Smith in favour of commissions recommendatory. The power of a scientific commission reporting without being cross examined must be invincible, and consequently a jury would cease to be of value. We must have all the aid of intellect and science, but we refuse its despotism and oppression. When both sides are heard the juryman has the advantage of both arguments; when clear he becomes convinced; when uncertain he has abundant reason for reposing on his perceptions or instincts. A jury of *experts*, the doctor thinks, would introduce too much law and leave out mutual considerations — would increase formal law and diminish instinct — would enlarge the head of the court and leave no room for its heart. Reviewing the position of the scientist as witness at great length, the lecturer advocated the admission of written scientific evidence upon which the witness may be examined and cross-examined if necessary. We gain by this means a clear and full statement which will not be stopped conveniently at every dangerous spot, but will either tell the truth, the whole truth, and nothing but the truth, or leave the witness to take his chance of receiving the character of a perjurer. The lecturer concluded as follows:

"This lecture has been in favour of giving the scientific man an independent position in a court of law. He becomes a court of appeal in himself, used equally by both plaintiff, defendant, and judge. On the one side, the plaintiff has the advantage of his knowledge and opinion, having made him well acquainted with the case, and been instructed in all its relations to science. The same advantage is given to the defendant, whilst an adviser, able by his education to encounter that class of reasoning, is given to the judge. Scientific men are bound together by mutual beliefs in a stronger manner than the community at large, and if put into this honourable and independent position, they will act according to their knowledge and character, and cease much unnecessary contradiction and opposition. Being bound to speak the truth, the whole truth, and nothing but the truth, they will feel in honour bound to do so when an opportunity offers. This opportunity rarely occurs in the present confusion.

My belief is, that no class of men will so fully agree with each other as the scientific, if not kept separate by the present corrupting system, and no class will spread a more beneficial influence over society if not contemptuously compelled to herd with thieves and scoundrels in a witness box. Perhaps this expression is too strong, but it has a side of truth; and I have seen barristers speaking to a scientific witness in a box in such a way as to show that a witness was to them always an inferior personage. This too happens even in cases where the word of the scientific man must of necessity decide the whole case, and where the duty of the barrister is a mere simple formality.

I think a scientific man may well claim for himself such an exemption from insult. You may say that his own character and bearing ought to command respect, but there are few men, if any, in this world, whose treatment by others is entirely unaffected by position.

We have now gone through the main points to be discussed according to this view of the case, and concluded that:—

1st. The scientific man shall not take the place of judge; the study of physical science does not fit a man for that office.

2nd. He shall not take the place of a jury, because the jury represents the instincts and impulses of intelligent freemen acting out the common sense of the community, an element essentially distinct from any physical science.

3rd. He shall not act as a plenipotentiary commission, absorbing judge and jury, for the above reasons.

4th. He shall not act as a recommending commisson, as such is apt to become too powerful, and really does become so in practice. Nos. 3 and 4 are plans of despotic states.

5th. He shall not act as advocate, because he represents fixed law, not the interests of individuals.

6th. If he acts as witness he must be allowed to express his opinion independently of the advocate, or the plaintiff and defendant. Put upon his own honour, he will be able and willing to speak the truth, the whole truth, and nothing but the truth, which is now not permitted him.

7th. He shall assist the judge in examining scientific witnesses, or obtaining scientific evidence as assessor.

8th. That instead of witness he may appear in his own character of scientific man, whose evidence is different from ordinary witnesses, and whose position is capable of being made, to a great extent, independent of the parties in the suit. This allies itself with No. 6.

The Remedies Proposed.—1st. To have a scientific assessor on the bench beside the judge, who shall examine the witnesses, if needful, and who shall advise the judge. That this assessor shall be appointed by the crown. He shall not be questioned as a witness, but sit as assistant judge.

2nd. That a position be given to the scientific man indepen-

dent of the barrister. I am not a lawyer, and do not pretend to adjust the mode of doing this, but I believe it is essential, and must be done sooner or later.

3rd. That scientific men giving evidence on scientific points shall be allowed to deliver their examinations in writing. The reading and elucidation to be controlled by the judge, examination and cross-examination by the barrister to follow. The subject is now arranged ready for your examination. It may be viewed in many ways—indignantly, humorously, and comically. I have endeavoured to view it calmly. The purely legal view must be left to the legal profession. Minute particulars and the practice of foreign states are necessarily left out."

Another suggestion, from the pen of Mr. Wentworth L. Scott, appears in the *Journal of the Society of Arts*. Commenting on the above paper, the writer continues:

"Were these several suggestions carried out something would yet remain to be done, for it must be remembered that a scientific jury is not to be thought of, and one composed of ordinary individuals is somewhat apt to forget (as being partly beyond its comprehension) in consultation various scientific points that have been impressed upon it while in court, or, at least, does not accord to them their full moral power. A very glaring instance of this was exhibited in the late trial of Dr. Smethurst, for (in the opinion now, I believe, of the country at large) if due weight had been given to the chemical and medical evidence, and the same had been properly considered, the verdict would have been different. Now, I would humbly suggest, for the consideration of those who are interested in the subject, that this defect might be remedied in one of the two following ways, viz. either (in all cases likely to require the same) by appointing as one of the jurors a scientific man, capable of giving to the said points their real and just value, and of explaining the same to his colleagues, or by allowing such a person to have access to the jurors, who may gain from him the information they require, while he is restricted to the simple answering of queries, without referring to his personal opinions on the case. Furthermore, ... I should be inclined to suggest that a special committee be formed .... for the purpose of more fully considering the subject of 'Science in our Courts of Law,' and that the barrister, the chemist, and the physiologist be equally represented amongst its members. The functions of such a committee would be various and important; some of the most prominent would be to consider and digest the whole subject in its legal bearings as it now stands; to point out in detail the defects of the present system, and the manner in which these might be most readily and conveniently done away with; to consider carefully the various methods of detecting poisons and adulterations now usually employed, noting the practical desiderata apparent therein; and, finally, to draw up a comprehensive report on the whole, calculated to serve as a basis for a parliamentary bill for amending the position of 'science in our courts of law,' to be brought before both houses."

CHEMICAL SOCIETY, 19 *Jan.* 1860.

PROFESSOR BRODIE, *F.R.S. President, in the Chair.*

AFTER the routine business had been disposed of

The CHAIRMAN stated that that evening being devoted to metallurgical chemistry, he would call upon Mr. Warrington to read his paper *On Refining Gold, when alloyed with Tin or Antimony, so as to render it fit for the purposes of Coinage.* In 1857 Mr. WARRINGTON was called upon to analyse a specimen of Australian bar gold, which was said to have been obtained by the quartz crushing process. Outside it had the appearance of a golden hue, perhaps a little paler than usual; but when it was broken the fractured surfaces were seen to have a crystalline structure of a greyish-yellow colour. It was very brittle, and was found to have the following composition:—

Gold	92·40	
Silver	4·60	
Tin	2·00	with trace of antimony.
Copper	0·75	
	99·75	
Loss	0·25	

Many bars of the same kind had arrived, and had given a good deal of trouble to the refiners and also to the Mint; and 47,000 ounces had been returned to the Bank of England as unfit for the purposes of coinage.

Another specimen which Mr. Warrington received, having much the same appearances and being just as brittle, yielded on analysis:—

Gold	93·80
Silver	2·20
Antimony	2·28
Tin	1·40
Arsenic } Copper }	traces.
	99·68
Loss	0·32

It is evident that the presence of these alloying metals would not be discovered in the ordinary mode of assay by cupellation and quartation, inasmuch as they would be oxidised and carried into the cupel with the lead; and therefore, from the brittleness of the alloy, the subsequent operation of rolling would be impossible.

A question arose as to the origin of these metals: whether they were found associated with the gold, or whether they were introduced during the melting process. Gold and oxide of tin are found associated in stream works both in Ceylon and Cornwall, and a good deal of stream tin is brought from Australia. The presence of tin, therefore, might be anticipated; but how was the antimony in the second specimen to be accounted for? Mr. Warrington's impression was that it was introduced during a rough process of refining by sulphuret of antimony, and that for want of proper management the operation had not been perfectly carried out.

The use of sulphuret of antimony in refining is well known, and it will suffice to say, that if successfully applied it converts the iron, zinc, tin, &c. with some of the silver, into sulphurets, which float on the surface of the gold. Some of the antimony, however, alloys with the gold, and must be removed by a second operation.

To find an inexpensive method of removing these alloying metals without a loss of gold required some consideration, inasmuch as it must be accomplished by a process of oxidation; and yet it was necessary that the oxidising agent should be applied to the gold while in a fluid state, and moreover, that it should not part with its oxygen simply by the heat to which it would be submitted. The use of nitrate of potash had failed, and therefore Mr. Warrington resorted to the employment of metallic oxides having a weaker affinity for oxygen at high temperatures than the metals it was necessary to remove from the gold.

After a few experiments Mr. Warrington determined on the process which he now laid before the Society. It consists in employing about ten per cent of oxide of copper, and a small quantity of borax, which with the alloyed gold must be kept in a well-fused state for half an hour. The result is a perfectly malleable gold containing a small per centage of copper and well fitted for the purpose of coinage. The amount of oxide of copper used must depend on the amount of oxidable metals to be removed; but from the specimens Mr. Warrington examined he thinks the proportion need never exceed ten per cent. Oxide of manganese might be used, but oxide of copper has many advantages over it. So prepared the resulting gold will always be better than standard gold, unless the baser metals are present in large proportion.

The solution of the above specimens in aqua regia deposited beautiful crystals of chloride of silver, and Mr. Warrington mentioned a curious case of the same kind, which had been brought under his notice by Mr. Scanlan. On trying to obtain the gold from a chain of Indian manufacture, by solution in aqua regia, Mr. Scanlan found that it would not dissolve. A little gold was found in solution, but the form and size of the chain remained unaltered. It had, however, become very brittle, and of a brown colour. Examination by the microscope showed what had happened. The chain now consisted almost entirely of chloride of silver, beautifully

crystallised on the surface, and having a radiating structure from the interior to the circumference. In some parts a fragment of the original alloy was found, which had probably been protected from the action of the acid by the chloride of silver formed around it.

In the discussion which followed, a MEMBER stated that sulphuret of antimony occurred in an enormous quantity in the immediate neighbourhood of gold. He had picked out many specimens from the quartz.

Mr. MAKIN said he thought that tin also might be present, and he thought that those bodies — tin and antimony — the latter more especially — would be got rid of in the ordinary refining process. He thought that the refining process with nitrate of potash could not be well employed because the density of liquid gold would prevent its complete action.

Mr. DELARUE stated that it sometimes occurred in their manufactory, that when the sweepings of the floors where gold leaf had been used were melted up, it would occasionally happen that loose type got melted with it. He had himself attempted to remove the antimony during the process of refining, but without success, and it appeared to him that the method suggested by Mr. Warrington had many things to recommend it. The only metal which was introduced into the alloy by that plan was copper, which left the gold in an equally available form, whether it was in excess of the amount in standard gold or not.

Mr. MATTHEY called attention to one point, viz. that if the gold containing antimony were attempted to be purified by the oxide of copper method, in plumbago crucibles, the copper would be reduced to the metallic state by the carbon in the crucible instead of by the oxidation of the antimony. He believed that the purification might be effected by the use of sal-ammoniac; if gold, alloyed with baser metals, were melted with sal-ammoniac, the gold would become quite tough, owing to the sal-ammoniac, during evaporation, taking away the other metals. He thought, therefore, that this was a more simple process than Mr. Warrington's, and one more likely to succeed on the large scale.

The CHAIRMAN asked whether certain specimens of zinc, which were stated to have been found in a metallic form at Bendigo, had been examined.

Mr. PHILLIPS said that he had received a parcel of silver ore from Australia some time ago, which contained several pieces of metallic zinc. It was a question how they got there. He at first thought that they were placed there on purpose; but it might possibly have been native zinc placed there by nature.

The CHAIRMAN said that the specimens of zinc from Bendigo of which he had spoken were so extremely pure that he suspected they were *sowed*, as he knew that the trick of *sowing* gold was commonly resorted to, for the object of raising the price of plots of ground.

Mr. PHILLIPS had met with specimens in an arborescent form, very much resembling arborescent silver, which upon examination were found to be almost pure zinc.

Mr. WARRINGTON in reply to the observations of Mr. Matthey, said that it was certainly fatal to any process of oxidation to operate in a black lead crucible. When the melters came to him, after making a first trial of his proposed method, they said they had been quite unsuccessful, and had not succeeded in rendering the gold in the least malleable. Upon inquiry, he found that they had operated with the plumbago melting pots ordinarily used in their operations, and which were, of course, fatal to any process of oxidation. On performing the operation afterwards in pots fitted for oxidation they succeeded perfectly well. The waste of gold when a large surface is exposed, and where by *burning out* so large a proportion of metal the gold is liable to spurt, was a very heavy loss to the refiner; he had no doubt of the success of the process described in his paper, if properly carried out.

The CHAIRMAN, after expressing the great obligation which the Society was under to Mr. Warrington for his valuable paper, invited Mr. Makin to read his paper *On certain sources of loss of Precious Metals in some operations of Assaying*. When making a large number of assays of gold, and also estimating the silver, under circumstances which required that an extraordinary degree of heat should be employed, Mr. MAKIN was struck with the great loss of gold and silver. Satisfied that it was not entirely owing to "cupel absorption" he examined the contents of the iron flue of the furnace, which had only been used for the cupellation of gold assays, to see if any of the precious metals had been volatilised. Under the microscope the apparently carbonaceous matter from the flue showed yellow masses of oxide of lead, nodules of suboxide of copper, and minute grains of silver mixed with carbonised matter containing small grains of unburnt fuel. On analysis the metallic matters present were found to be oxide of lead mixed with small portions of gold, silver, and oxide of copper. The metals were extracted by lead in the usual way, and the button obtained by scorification was subjected to cupellation. The gold and silver were then parted, and the proportions of each in 1000 grains were found to be:—

Gold	0·087
Silver	0·763

Another source of loss occurs in parting operations and refining on the large scale, from the solution of gold in nitric acid, even when it is quite free from hydrochloric acid, in consequence of the formation of nitrous acid. Mr. Field, the Queen's assay master, had a bottle which was thickly coated with gold deposited from nitric acid which had been used in parting operations. Sir John Herschel thought that the gold might have been suspended in the acid; but the fact that the bottle was pear-shaped, and was uniformly coated with the metal, proved that it must have separated from a solution. To ascertain the amount of loss from this source in ordinary assay operations, Mr. Makin took four specimens of pure gold accurately weighed, added the usual proportions of fine silver and lead, and then cupelled them. The resulting buttons were rolled, coiled, and parted with nitric acid, the cornets being boiled in two acids of different strengths a different number of times. Calling the weighings before the operation 1000, the results were as follows:—

1.	Boiled in acid twice	999·6
2.	„ 3 times	999·2
3.	„ 4 times	998·7
4.	„ 5 times	997·9

The loss is thus seen to increase as the boilings are multiplied.

When silver is present in large quantity, Mr. Makin believes that the solvent action of nitrous acid is restrained by electrical action, the gold becoming the negative and the silver the positive pole of a circuit; but as the silver is removed, the solution of the gold goes on more rapidly. The cause of the evolution of nitrous acid is evident as long as there is any silver present, and it often results from the use of charcoal to prevent "bumping." When charcoal is thoroughly carbonised, it does not materially affect the acid; but if it contain woody matter, nitrous acid is sure to be set free. Mr. Makin has given up the use of charcoal on this account.

The commercial importance of this subject will be admitted, when we remember the enormous value of the metals dealt with in this country, and that the question of profit and loss in commercial transactions with them are almost entirely in the hands of the assayer. A knowledge of these facts may also serve to account for some of the discrepancies between assayers.

The CHAIRMAN stated that Mr. Makin had very much underrated the value of his paper in a commercial point of view. It was well known when platinum was alloyed with silver it was readily dissolved by nitric acid, and the same thing might therefore take place with gold.

Mr. MAKIN thought that the solution of the gold was due to nitrous acid, because the effect seemed to be increased as the silver decreased.

A Member thought that the fact of the volatilisation of of gold and its deposition in the chimney of the furnace was very important. In great smelting works, where the flues are carried up for several miles among the mountains, large deposits of metals are found in them.

The Chairman recollected some lead works which had that description of flue, and he was told as a fact that the whole profit of the works was said to lie in the metal so recovered in the flues.

Mr. Phillips asked Mr. Makin whether he had taken any notice of the absorption of the metal by the cupel, which sometimes amounted to from 5 to 10 per cent., a matter of very great importance in assaying. Being connected with some silver assaying works this subject had frequently been brought under his notice, and he found that the cupel absorption sometimes amounted to as much as 11 per cent. Of course a great deal would depend on the shape of the cupel.

Mr. Makin said that the absorption by the cupel was a fact so well known that he did not think it necessary to mention it. He was very careful on this point, so much so, that he had all his cupels made by the same hand, in order that he might have as little difference of absorption as possible, and this was estimated and allowed for by calculation; but even then it varied sometimes.

The Chairman asked whether Mr. Makin had made any experiments with a view to see whether nitrous acid effected the solution of gold when other foreign metals beside silver were present.

Mr. Makin said he had not at present.

[Owing to the length to which our report extends we are compelled to defer the notice of Mr. Field's communication till next week.—Ed.]

NOTICES OF BOOKS, PATENTS, &c.

Improved Method of obtaining the Metallic Particles contained in Fumes or Vapours from Lead and other Smelting Works. Alfred Courage.

Mr. Courage introduces steam into the flue or flues communicating with the various furnaces, which, mixing with the fumes, causes the deposit therefrom of the metallic particles contained therein or therewith. He claims the introduction of steam into the flues, and the placing of tanks in them to utilise the waste heat in generating the steam.

Improvements in producing Figures or Representations upon Glass. James Napier.

Mr. Napier takes a print, lithograph, or engraving, or design, drawn by hand with printer's ink, and fixes the *printed surface* to the glass by means of ordinary paste, with great care to exclude the air. When perfectly dry, he applies to the paper liquid hydrofluoric acid, specific gravity 1·14 for about three minutes, after which he washes off the paper, and the figure or representation is found on the glass. Of course the printer's ink protects the glass from the action of the acid. Mr. Napier prefers to have the glass finely ground, enamelled or veneered, before he applies his process, when the picture stands out in relief. If the veneer or enamel is coloured, of course the picture remains coloured, and the body of the glass is white. Very pretty effects may no doubt be produced in this way.

Improvements in the purification of Coal Gas. John Leigh.

Mr. Leigh's invention consists in the application of causticised or partially causticised gas water or ammonia water to the purification of coal gas or cannel gas in order to remove from the gas not only the salts of ammonia existing therein, but also the carbonic acid, sulphuretted hydrogen sulphocyanic acid, hydrocyanic acid, &c. which may exist also in the impure gas. He gets his causticised gas or ammonia water by mixing these liquids with slaked lime and agitating the mixture for a considerable time. When the lime is deposited, the clear solution is run off, and pumped to the top of a washing tower, where it is made to fall in a shower or spray upon a number of shelves covered with brickbats or other material exposing extent of surface through which the gas which enters at the bottom is made to pass. The gas, says the inventor, being brought into contact with the causticised ammonia water, imparts to it not only the salts of ammonia which it contains, but also the carbonic acid, sulphuretted hydrogen, sulphocyanic, and hydrocyanic or other acids which may exist in gas as impurities. *But* as some portion of the salts of ammonia *may* be carried forward, these may be removed by passing the gas terminally through one or more purifiers containing layers of any one of the numerous substances capable of removing the salts of ammonia. The inventor desires it to be distinctly understood, that he claims nothing but the use of causticised or partially causticised gas water or ammonia water for the purification of coal or cannel gas.

CORRESPONDENCE.

Druggist's Labels.

To the Editor of the Chemical News.

Sir,—Your correspondent Cui Bono (p. 71) inquires the use of Latin labels. I beg to answer: 1, That they secure intelligence, and preparatory education in chemists and druggists who dispense the medicines so named. 2, That they keep up the profits of the drug trade, and secure for it the cream of middle class young men. 3, That they secure the *faith* of invalids. 4, That they promote scientific literature. Many other reasons I could have urged, but these will probably suffice. It may be safe to use English labels when the multitude understand the character and properties of strychnine as well as they do those of gunpowder, or those of Hyd. Bichlor. as well as the uses of saltpetre; but until then we had better use Latin labels.—I am, &c.

T. S.

Chemical Notices from foreign sources, by Dr. T. L. Phipson.

I. MINERAL CHEMISTRY.

Chrome-green.—M. Guignet[1] has discovered a new method of preparing oxide of chromium fit for colouring purposes. A mixture of 3 parts of boracic acid and 1 part of bichromate of potash is calcined at a temperature of about 500° (Centigrade). An evolution of water and oxygen gas is observed, and there is formed a double borate of sesquioxide of chromium and potash. This salt, which is stable at the ordinary temperature, is decomposed by water, giving bi-borate of potash and sesquioxide of chrome. The latter in the nascent state combines with water, and forms an hydrated sesquioxide of a remarkably fine colour. This is separated from the biborate of potash by decantation and washing, and the resulting chrome-green has been introduction into commerce either as an oil paint or for the use of calico-printers. In the former case it is first dried and then reduced to powder; in the latter it is directly introduced into the bruising machines. This colour is very solid and brilliant, even by artificial light.

Antimoniuretted Hydrogen.—Dr. Hannon, professor at the University of Brussels, has published[2] a note upon the pharmaceutical preparation and administration of antimoniuretted hydrogen. When pure, antimoniuretted hydrogen is a colourless gas, having no odour, and which does not irritate the bronchiæ; it can therefore be introduced

[1] *Le Cosmos*, 30 Déc. 1859.
[2] *Journal de Pharmacologie de Bruxelles*, Jan. 1860.

into the lungs without danger. It burns with a yellow flame, evolving white vapours of oxide of antimony. When a cold body is placed in this flame, a black opaque coating of metallic antimony is deposited upon it. This deposit differs, as is well known, by many characters from a similar one, which is produced by arseniuretted hydrogen. Antimoniuretted hydrogen can be passed through water and through alkaline solutions without decomposition. For therapeutic purposes Dr. Hannon recommends that it should be prepared with 9 grammes of an alloy composed of 6 parts of zinc and 3 parts of antimony. To these 9 grammes are added 3 grammes of tartar-emetic or the same quantity of chloride of antimony. The zinc and the antimony employed must be chemically pure. The above mixture is placed in a flask with a wide neck, and to it is added from hour to hour, when the invalid is to inhale the gas, 2 or 3 grammes of hydrochloric acid until 30 grammes of the latter have been used. As hydrochloric vapours are evolved at the same time, it is necessary to fill the neck of the flask with a sponge containing a solution of potash or soda to arrest the acid vapours. By means of a piece of string attached to it, this sponge is withdrawn after the inhalation has taken place. The antimoniuretted hydrogen is inhaled by the patient for five minutes each hour. After an inhalation has taken place the flask may be left in the room uncorked, that the antimoniuretted gas may mix with the air of the chamber.

II. ORGANIC CHEMISTRY.

On Melampyrin; a new kind of Sugar. — This new immediate principle has been lately studied by M. Eichler.[3] It was formerly obtained in an impure state by Hunefeld. M. Eichler describes three processes by which it may be extracted; the following is the most simple: —

A decoction is prepared with the leaves of *Melampyrum nemorosum*. It is boiled with milk of lime and then filtered. The clear liquid is evaporated, and hydrochloric acid is added until an acid reaction is obtained; the melampyrin is soon deposited in rhomboidal prisms. These crystals are transparent and inodorous; their sweet taste is less marked than that of lactin (sugar-of-milk).

Melampyrin is also found in two other plants that are common enough in our climate, namely, *Scrophularia nodosa* and *Rhinanthus cristagalli*.

The three plants named all contain *succinic acid*, whence it is possible that melampyrin does not exist in these plants in a separate state, but in combination with this succinic acid, forming what is called a *glucoside*. This opinion, however, has not been expressed by M. Eichler.

Melampyrin is very soluble in boiling water, from which a portion is deposited on cooling; 1 part can be dissolved in 25·5 parts of water at +15° (Centigr.), and in 1362 parts of alcohol of 0·835 sp. gr. It is very slightly soluble in acetone, wood-spirit, acetic ether, and chloroform. Completely insoluble in ether, benzin, turpentin, and oil of naphtha. Melts at +186° (Centigr.) without losing any of its weight. Its solutions have no action upon polarised light. It resists boiling with weak potash or dilute sulphuric acid; does not reduce either salts of copper or mercury in presence of potash, and is not changed by a mixture of bichromate of potash and sulphuric acid.

Nitric acid only decomposes melampyrin at boiling point; the products are *oxalic acid* and *mucic acid*. When treated with sulpho-nitric acid melampyrin produces several nitrogenous compounds, which explode slightly when heated, and from which melampyrin can be again obtained by reducing the compound with sulphide of ammonium. Melted at 186° (Centigr.) melampyrin presents a composition which corresponds to the formula: $C_{12}H_{18}O_{18}$, which only differs from mannite by 1 eq. of water. With oxides it forms compounds similar to those formed by mannite and cane-sugar. The baryta compound is $C_{12}H_{16}O_{13}$, $2BaO$, $14HO$; it forms hexagonal prisms, which are very soluble in water and dilute alcohol. By means of this compound and carbonate of ammonia, the corresponding ammonia compound is prepared by double decomposition. It also crystallises in hexagonal prisms.

Finally, melampyrin dissolves in concentrated sulphuric acid, giving a vinic acid, whose baryta salt is very soluble in water, and insoluble in alcohol; its formula is $C_{12}H_{12}O_{10}$, $3BaO$, $6SO_3$.

III. CHEMICAL ANALYSIS.

Separation of Zinc from Nickel or Cobalt. — M. Brunner[4] gives us the following solution of this problem, which was formerly looked upon as one of the most difficult in analytical chemistry — the solution of the two metals (zinc and nickel, or zinc and cobalt) in hydrochloric or nitric acid, is diluted with a large quantity of water, and almost completely neutralised by carbonate of soda. To effect this, a slight excess of the latter is added, and the precipitate which ensues is redissolved in a few drops of acid, so as to introduce a very slight excess of the latter. A current of sulphuretted hydrogen is then made to pass through the liquid, and to complete the precipitation of the zinc, a few drops of a diluted solution of acetate of soda are added to the liquid. Care must be taken not to introduce an excess of acetate, and not to heat the liquid. A fresh current of sulphuretted hydrogen is now allowed to pass, until the precipitate does not appear to increase. The vessel is then left to itself for ten or twelve hours at the ordinary temperature, after which the precipitate is collected in a filter and washed. To make sure that all the zinc has been thrown down, a drop of acetate of soda may be added to a little of the filtered liquid, which should remain clear, when a little sulphuretted hydrogen is introduced. The nickel or cobalt is thrown down from the filtrate by potassa.

If the original solution contain iron, it is essential to separate it first of all by carbonate of baryta, as proposed by Fuchs.

SCIENTIFIC NOTES AND QUERIES.

Magnetic Peroxide of Iron.—Sir,—Perhaps you will allow me to direct the attention of your correspondent, Mr. Robbins (p. 11), to Brande's *Manual of Chemistry*, vol. i. p. 715, where he will find the following remark on peroxide of iron: "When, however, it has been long and strongly heated, portions of it sometimes become magnetic."—*W. G.*

Sir,—At p. 262 of Dr. John M'Culloch's *Essay on Malaria*, a work of authority and much value, published in 1827 by Longman and Co. of London, is the following passage:—"That guns which had been reposing for a century at the bottom of a deep sea, were *red-hot* when brought up to the light of day was as little believed and as much ridiculed as the limitations of the malaria in this case will probably be by the sceptics in question. Yet the investigations of the same credulous person proved its truth, and added a new and interesting fact to chemical science."

Of the curious matter alleged so positively but obscurely in the foregoing quotation, he nowhere else in his work offers either detail, or proof, or explanation; and yet from his character and position he was not a man to make a gratuitous mis-statement. If what he has so enigmatically asserted is indeed a fact, it will well deserve to be added to the number of "The Hot Contradictions."

You will greatly oblige one of your readers and subscribers if you will have the goodness to say whether: 1st, the matter alleged by the doctor is indeed a fact; and, if indeed a fact, in what book an account of it is to be found; and 3rd, what is the explanation of it?—*J. Moorhead.*

[We have never seen the statement except in Dr. M'Culloch's work; but perhaps one of our readers may be able to say what has been the origin of so extraordinary a report.—Ed.]

Ignoramus wishes to know "What are the reasons for considering the formulæ at present given for the acid and other bodies obtained from lichens by Stenhouse as doubtful?"

LABORATORY MEMORANDA.

Results of the working of Cod-fish for Fibrin, &c.—Six large fish were taken—the flesh of which carefully separated from the skin, bones, &c. weighed 43 lbs. avoirdupois. The flesh was chopped very fine, kneaded with water and subjected to pressure in the usual way—a process which was repeated several times—by which means was obtained as the final result:

Dry fibrin	4 lbs. 10 ozs. (avoir.)
Dry albumen	10 ozs. ,,
Kreatine	327 grs.
Phosphoric acid	1·589 oz.

The above is not given as an analytical estimation of the above ingredients in the flesh, but merely as the results of a commercial working.—*John Williams.*

MISCELLANEOUS.

Homœopathic Dilutions.—You frequently see in homœopathic writings that the billionth of a drop was used. What is a billion? A million times a million. No man could count a billion. If you counted 200 in a minute, this would be 12,000 in an hour, 288,000 in a day, and 105,120,000 in a year—it would take 9512 years, at the above rate of 200 a minute, to count a billion! And yet this is only the sixth dilution used by homœopaths, viz. the 1,000,000,000,000th of a drop or grain. Some, however, will dilute their medicines to the decillionth part of a drop. We endeavoured to show that the Atlantic Ocean does not contain a decillion of drops, and that the physician might as well drop a drop of laudanum or any other medicine into the sea, and after being *well mixed* take a few drops out and give them to his patient.—*Braithwaite's Retrospect.*

The Fitzmaurice Light and Portable Gas Company.—An exhibition of this new light—the Oxyoleofiant—took place at Conway Lodge, Hyde Park. The light, which is composed of camphor and vegetable oils, has all the softness and brilliancy of gas, without its heat or deleterious effluvia. It can be produced at the price of the ordinary coal gas, and one great advantage in connection with it is that every large establishment or householder can be furnished, at a cost of from 5*l.* to 10*l.* and upwards, with his own gas-making apparatus on his own premises.

Poisoning by Hydrochloric Acid and Chloride of Zinc.—Last week a girl was admitted into the London Hospital who had swallowed about two ounces of the following solution:—hydrochloric acid 4 ozs., water 4 ozs., chloride of zinc 1oz. She died about eighteen hours after drinking the poison. The antidote used was magnesia given in milk at frequent intervals.

Pennsylvania Rock Oil.—In most countries, a troublesome process must be undergone to extract oil from mineral substances, such as from coal and asphalt; but Pennsylvania seems to be so favourably dealt with by Dame Nature that the very rocks distil oil into her lap. The north-western part of that State seems to contain a number of subterranean springs which yield a limpid oil, some of which we have examined. It appears that the Pennsylvania Rock Oil Company purchased the spring of Brewer, William & Co. for the sum of 5000 dollars; and, in 1858, leased it to Mr. E. L. Drake, with the understanding that he should gather the oil at his own expense and pay them 12½ cents a gallon for it. His lease extended for 15 years, with full privilege of working it at his own option. In May last, he commenced looking for salt, and after sinking a shaft 71 feet, on the first of last month, he struck a fissure through which he was boaring, and the discovery of the subterranean spring of oil was the result. The yield per day, up to the period of the recent fire, had increased from 400 to 1600 gallons. The tract of land on which this spring is located was once purchased for a cow, and previously it had been sold at the treasurer's sale for taxes. Now, it is believed, 100,000 dollars would not purchase one acre of it.

The substance known here as Seneca oil, exudes from the rocks, or floats on the surface of springs, in various parts of the world. The name of Seneca oil was derived from the Seneca Indians, a tribe famous in the confederacy known as the Six Nations. The oil in this county was discovered and used by this tribe. A similar oil is found in abundance at Amiano, in Italy; Birmah, on the borders of the Caspian Sea; on the West India Islands, along the shore of the Kanawha, Virginia; in Kentucky; near Seneca Lake, New York; in western Pennsylvania, generally; and in great abundance in Venango county. The wells of Birmah yield 400,000 hogsheads annually. Its uses are almost end less. As a medicine, it is used both externally and internally; is regarded as an excellent stimulating embrocation in chilblains, chronic rheumatism, affections of the joints, paralysis, and kindred complaints. It is an ingredient in the celebrated British oil. It is also used for making an excellent lamp oil, known as Carbon oil, and is considered among machinists as the best lubricator extant.—*Scientific American.*

Detection of Blood Stains.—M. Brucke has recently published the following method, as being superior to those in common use:—"Wash the spot with cold distilled water. To the reddish liquor thus obtained add a solution of sea salt, and evaporate to dryness, *in vacuo*, over a vessel containing sulphuric acid. Examine the dry residue well through a microscope, in order to verify whether it contains any matter that might be mistaken for Tetchmann's crystals; then add a little highly concentrated acetic acid; evaporate again to dryness; moisten the residue with water; and then, if there really be blood in the spots, the microscope will reveal unmistakable crystals of hæmatin."

ANSWERS TO CORRESPONDENTS.

J. G. (Stourbridge).—We do not know any work which seems to be exactly what our correspondent wishes for.

J. B.—It is much to be regretted that regulations exist which deprive such a deserving case of the assistance of the fund. We will think over the matter, and when space permits perhaps publish our correspondent's letter.

R. J. S.—Not without spoiling the flavour. It must be distilled.

Physeos Zetetes.—1. We do not know the work, but will look at it. 2. Any book on organic chemistry.

An Assistant.—We should be very happy to assist the early closing movement if we could.

Credo.—1. A mixture with acetum scillæ and sesquicarbonate of ammonia is of course "unchemical." 2. You might mention it to the prescriber.

A. B. F.—A saturated solution of sulphate of soda in boiling water, allowed to cool in a flask or bottle from which air is carefully excluded, and then left perfectly still until the experiment is made.

J. Horsley, F.C.S.—Expert—A Member—Oxygen—F.G.—received.

Book received.—Stories of Inventors and Discoveries in Science and the Useful Arts. A Book for Old and Young. By John Timbs, F.S.A.

VOL. I. No. 9. — February 4, 1860.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Estimation of Phosphoric Acid in Manures, Coprolites, Bone-ash, and similar Commercial Substances, by FRANCIS SUTTON, Norwich.

PHOSPHORIC acid may appropriately be estimated as pyrophosphate of magnesia, basic phosphate of magnesia ($3MgO.PO_5$), phosphate of lead, basic phosphate of iron, phosphate of binoxide of tin, phosphate and pyrophosphate of silver, and lastly as phosphate of uranium.

There can be no doubt that of the above-mentioned forms in which to weigh phosphoric acid, the pre-eminence is generally given to pyrophosphate of magnesia in point of accuracy; but, on the other hand, the difficulties which beset the process in the case of substances mentioned at the head of this paper are so numerous and perplexing, that it is worth while to look for some other method by which the same end can be attained without the expenditure of so much time and trouble.

Without noticing in detail the other processes mentioned, except to say that they are all more or less open to objection, either on the ground of inaccuracy or consumption of time, I will at once come to the last on the list, that is to say, phosphate of uranium, which I believe to be equally accurate with pyrophosphate of magnesia, and far preferable to it in readiness of application and general convenience.

This process was first announced by Leconte[1], since which MM. Arendt and Knop have carefully tested its accuracy and more fully developed the method of application.[2] Fresenius also, in the last German edition of his *Quantitative Analysis*, mentions the process as in every respect satisfactory for the purposes here alluded to. Of the chief advantages connected with the use of salts of uranium as a means of estimating phosphoric acid in phosphates of lime, &c. is that the presence of bases does not interfere with the result. The bases which admit of this mode of determination so far as present experiments have proved, potassa, soda, lime, baryta, magnesia, iron, and alumina; the latter only, however, with modifications of the process as applied to the former. These modifications will be noticed by and by.

In the presence of potassa, soda, magnesia, lime, and alumina the following course must be adopted:—

The substance is to be dissolved if possible in acetic acid; however, this is not to be done, a nitric, hydrochloric or sulphuric acid solution is admissible, taking the caution to avoid any great excess of acid; add soda in excess, and redissolve the precipitate in acetic acid; in the presence of mineral acids it is advisable to add acetate of ammonia as well as acetic acid. Lastly, add a solution of acetate of uranium (best obtained by dissolving pure ammonio-carbonate of uranium in acetic acid) and heat to boiling, by which means the phosphoric acid is completely separated as phosphate of uranium and ammonia.

This precipitate is of a greenish-yellow colour and somewhat slimy in its nature, therefore in order to prevent the pores of the filter from being choked by it, it must be handled in the following manner:—After boiling, set aside on the sand bath, and allow the precipitate to settle; when the supernatant liquid is clear, decant through the filter, pour water over the precipitate and again boil for a few moments; decant as before, taking care that the precipitate has entirely subsided; repeat the process three or four times until the sliminess of the precipitate has given place to a feathery appearance, then pour it out upon the filter and complete the washing in the usual way.

The above process may be hastened somewhat by adding to the liquid in which the precipitate is first suspended, after it has somewhat cooled, a few drops of chloroform; then vigorously stirring the liquid or boiling it up once or twice causes the precipitate to settle more rapidly.

The phosphate of uranium and ammonia thus obtained is totally insoluble in water and acetic acid, but easily so in mineral acids; the addition, however, of a sufficient excess of acetate of ammonia throws it down completely again on boiling. On burning the precipitate the ammonia is driven off, and a lemon-coloured phosphate of sesquioxide of uranium is obtained possessing the formula:

$$2(Ur_2O_3),PO_5$$

If, however, carbon or any reducing gas is present during the burning of the precipitate it is partly reduced to phosphate of protoxide of uranium of a green colour; but on moistening it with nitric acid and again heating the yellow colour of the higher oxide is reproduced.

It is therefore advisable in burning the precipitate to separate it from the filter, first burning the latter, then adding the former, and heating to redness until every trace of carbon is removed. As a precaution against partial reduction it is advisable in all cases to moisten the precipitate when cool with nitric acid and again heat to redness. The burning may take place in an open platinum crucible, and as the precipitate is not easily hygroscopic it may be weighed uncovered.

If it should be necessary to redissolve the precipitate in order to estimate the phosphoric acid afresh, the solution must first be preceded by smelting the precipitate with a considerable excess of carbonate of soda so as to convert the pyrophosphoric into tribasic phosphoric acid.

The composition of the phosphate of uranium is as follows:—

		Per cent.
$2Ur_2O_3$	285·6	80·01
PO_5	71·0	19·99
	356·6	100·00

---

[1] *Jahresbericht*, von Liebig und Kopp für 1853, p. 642.
[2] *Centralblatt*, 1856, 769, 803, und 1857, 162, 177.

Therefore one fifth of the precipitate may be calculated as phosphoric acid.

During the past year I have used this process for the determination of phosphoric acid in guanos, the so-called superphosphates of lime, bone-ash, coprolite, &c. in above a hundred analyses, and in many of them controlled the results by other methods, without one instance of inaccuracy or failure. In the more delicate process of urinary analysis I have found it equally reliable.

In a future number will be given the modifications of the process necessary in the presence of oxides of iron and alumina.

TECHNICAL CHEMISTRY.

Extracting Silver from its Ores.

THE processes now in use at the reduction works of the Sonora Exploring and Mining Company, for the extraction of silver from the ores, are essentially three, viz.: smelting, amalgamation in barrels, and amalgamation in the open air, or the *patio* process. They are briefly described by Mr. F. Brunckow, who has recently returned from Arizona, in a report to a committee of the stockholders, from which the following is in part extracted:

The ores of the Heintzelman vein, as well as most of the Mexican ores, contain a considerable portion of quartz, which renders them difficult to smelt. The richest portions only are therefore selected for the smelt-process.

The lower part of the furnace is built of a fine-grained refractory quartzose sandstone found in the neighbourhood. The upper part and the smelting-house are built of brick, dried in the sun and air, called *adobes*. The smelting chamber inside the furnace is twelve inches square, and the blast is produced by a double bellows constructed at the place and worked by one man.

To each part of selected silver ore, three parts of lead ore from the Arenilla mines are added, and after complete fusion the contents of the chamber are allowed to run off into a basin on the outside. As it cools, a crust is formed on the surface, which contains to a large extent sulphurets of copper, lead, and the impurities. This is taken from the lead below and kept separate. The lead is run into castings in the form of cakes, ten inches in diameter, weighing 75 pounds. Six of these lead cakes are put on edge, one near the other, upon two inclined iron plates, which nearly touch each other. Charcoal is placed around and between the cakes, so that they are enveloped, and after kindling it the lead cakes must be protected from draughts of air. The heated cakes commence to melt and sink, and the lead runs down the iron plates to a basin, from which it is run into pigs. The lead is free from copper, and yields about 40 pounds of silver to the ton. A skeleton of each lead cake is left behind on the iron plates, and is rich in copper, and yields some silver. In order to separate this from the copper, the skeleton is broken into fragments and passed the furnace in company with the crusts taken from the lead in the first place, and with some other lead ore. By smelting the skeletons and crusts, which contain sulphurets, &c. lead will result, which is put in castings in the form of cakes; these cakes are put again upon the inclining plates, and pass through the process described before. The remaining skeletons this time contain very little silver; they are smelted in a copper refining reverberatory furnace and refined, and in the form of balls of metallic copper are delivered over to the amalgamation works, where they are required for the barrel process.

The argentiferous lead, free from copper, is put in a cupellation furnace, and passes the well-known oxydating process; the silver remains, and is refined. The resulting oxide of lead is added to the lead and silver ore, and again passes the blast furnace.

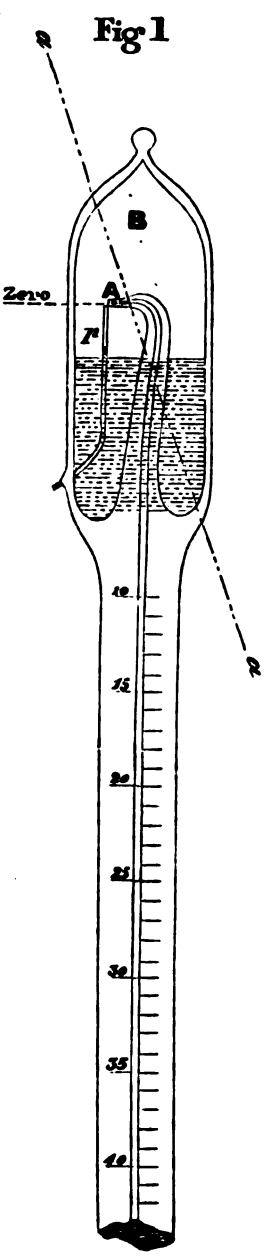
To prepare the ore for amalgamating in barrels, it is crushed by stamps, and passed through three sieves. The siftings of the first sieve are put under the stamps again. The sifting of the second sieve is as fine as grains of wheat, and the total sifting is delivered to the ore-mill, Arastra, where it is ground with water to a very fine powder; then it is dried and crushed. The sifting of the third sieve gives a powder fine as flour. This powder and the obtained fine-ore powder of the Arastra mill is mixed with 8 per cent. common salt, put in a reverberatory roasting furnace, and roasted till all the metals are formed into chlorides; this process is completed in 5 hours. Eight hundred pounds of this powder are put into the amalgamation barrel, together with a certain quantity of water and 75 pounds of the copper balls from the smelting furnaces. The barrels are then made to revolve, so that the whole mass in the barrel will form, after a certain time, a paste so stiff that the 400 pounds of quicksilver now added will not remain in a separate mass at the bottom, but will be divided through the whole body of ground ore in minute globules, unseen by the naked eye. The barrels are now made to revolve for 22 hours. The formed chloride of silver will be precipitated into metallic silver by the presence of the metallic copper; chloride of copper will be formed, and this will be lost. The silver in the metallic state in contact with the quicksilver then forms the amalgam. After 22 hours, more water is put in the barrels, in order to thin the paste, and to accumulate the minutest globules of quicksilver and the formed amalgam in a mass. This will be accomplished in 2 hours, by allowing the barrels to revolve slowly. The barrels are now opened, and the quicksilver and amalgam runs out in troughs, from whence it is put into strong canvas bags. The surplus quicksilver is pressed through the bags by its own weight; the remaining stiff amalgam is retorted; the silver, not being volatile, remains, and is melted, and cast into bars. The bars are marked with the company's stamps, numbered, their fineness according to the assay, and their value in dollars marked upon them.—*American Mining Magazine.*

The Compensation Self-registering Maximum Thermometer of Mr. WENTWORTH L. SCOTT.

THIS very ingenious instrument "consists of a glass tube, with a cylindrical bulb, containing mercury (as in the ordinary thermometer), at its lower extremity; but at the top the stem is drawn out into a fine jet, bent at right angles, A in the interior of the second bulb, B; this upper bulb is about half filled with mercury, the remaining space being a vacuum; near its base a platinum wire, *p*, is welded into the glass, and bent upwards, so that its point is nearly in contact with that of the jet. It is obvious that when the instrument is 'set,' *i. e.* the lower bulb and capillary tube to the point of the jet, completely filled with mercury—any rise of temperature will expand the mercury and cause it to overflow in minute globules into the reservoir above. The platinum wire is simply for the purpose of preventing the forma-

tion of large drops at the point of the jet, by its superior attraction for the fluid metal. Upon cooling, the mercury now remaining will, of course, sink in the tube. The instrument is so graduated that if it were cooled to zero Fahr. the level of the mercury would precisely indicate the highest temperature to which it had been previously exposed; but if the observation were made at the atmospheric temperature, the mercury would stand exactly as much higher in the tube, *i. e.* lower in the scale—as the temperature of the air was above zero Fahr.; therefore, to ascertain the maximum temperature, it is only necessary to add to the degree at which the mercury stands the temperature at the time the observation is made. Thus, supposing the 'compensation' thermometer marks 35 deg., and an ordinary instrument by its side is at 50 deg., 85 deg. will be the highest temperature that has occurred since the last observation. To 'set' this thermometer, the lower bulb must be gently raised, until the mercury runs down the tube into the reservoir-bulb; when contact has been thus established between the two portions of the metal, the reservoir-bulb is slightly elevated, care being taken to keep the point of the glass jet under the surface of the metal (the dotted line *a a* in the diagram, " represents the level of the mercury during this operation). The mercury will now flow back into the lower bulb, and refill the small vacuum produced by the previous decantation, when, upon restoring the instrument to its original vertical position, the tube will be full to the extreme point of the jet."

Fig 1



This thermometer is especially adapted, and indeed was designed, for deep-sea observations. No motion can in the slightest degree affect its accuracy, for no moveable indices are employed, and when the mercury has once passed out of the jet it can only return when the instrument is placed in the position just described.

When used for deep-sea experiments the thermometer is placed in a gun metal tube, over which a cap of the same metal is tightly screwed.

PHARMACY, TOXICOLOGY, &c.

A new Method of estimating the Quinine in Cinchona Barks, by MM. Glenard *and* Guillermond.[1]

The therapeutical as well as the commercial value of a cinchona bark depends on the amount of quinine it contains. A great variety of barks are found in commerce which differ considerably in the quantity of the alkaloid they yield. It is very necessary therefore that every one who buys cinchona barks should know how their value may be tested.

Many methods have been given for estimating the amount of quinine in a bark, but all are tedious and dificult of execution, and consequently require more time and skill than many who are interested in knowing the value of a bark can give to the experiment. The authors therefore endeavoured to find out a method of analysis which should be exact, rapid, and so simple as to be practicable by every one; and they have invented a volumetric method which they believe is perfectly successful.

To extract the quinine they take 100 grains of the bark, place it in a porcelain capsule, add enough hot water to moisten the powder, and then leave it to swell. After some minutes they add by degrees the same weight of lime in fine powder, and then enough water to form a sort of paste, which must be well mixed by stirring with a glass pestle. The lime penetrates the bark, and by decomposing the salts of quinine sets the alkaloid free. The mixture is now thoroughly dried in a water bath, after which the quinine is dissolved out by a known quantity of pure anhydrous ether. Ether is chosen as the solvent, because it dissolves but a very small quantity of cinchonine, and has no action on the colouring matter or other principles in the bark.

To determine the amount of quinine in this etherial solution, the authors add a measured quantity of dilute sulphuric acid of known strength, and then shake the bottle strongly to bring the two well in contact. The quinine passes into the acid liquid, and is changed into sulphate, and at the same time a proportionate amount of acid is neutralised and disappears. To estimate the quinine, it suffices to know the amount of acid combined, or the quantity which remains free. This is found by means of a standard solution of ammonia, made of such a strength that one volume shall exactly saturate an equal volume of the acid. The acid liquid may be coloured with litmus and then the ammonia should be added from a burette: and when the point of saturation is attained, it is easy to see by the quantity of ammonia remaining in the burette the amount of sulphuric acid which has combined with the quinine, and from these data the proportion of the alkaloid contained in the bark may be calculated.

This method, the authors think, realises the conditions of rapidity, precision, and easy execution, they had in view, since by its means any one not used to chemical operations may in less than an hour estimate the value of any bark. Quinometry, they say, presents no more difficulty than alkalimetry.

Many objections to the process have already been made. It has been said, that the equivalent of sulphuric acid being very small in relation to that of the quinine, a small error in the valuation of the acid solution will involve a grave mistake in the sum total of quinine.

[1] Abridged from the *Journal de Pharmacie et de Chimie*, Jan. 1860.

This objection is evidently not serious. It is easy by operating with care to avoid being deceived.

It has also been said that *quinidine* is so soluble in ether, that it may be the cause of a serious mistake — so much so that a bark which does not contain any *quinine* at all may be estimated to furnish three per cent. This might be true if barks usually contained quinidine. In that case the process would certainly give false indications. But does quinidine really exist ready formed in the bark? is it necessarily given birth to every time the bark is submitted to solar action? The authors do not think it. Although the salts of quinine exposed in a glass or capsule to the direct rays of the sun may change into quinidine, it does not follow that the same alteration is produced by the same influence on the quinine contained in vegetable pores and cells. At the most they believe that this modification takes place at the points where the tissue of the bark has been torn; but then the production of quinidine is so inconsiderable in relation to the mass that the presence of the alkaloid in the liquid analysed will not sensibly influence the results of the analysis. They believe still less in the pre-existence of quinidine in the bark — having many times sought for it in vain; and think that this want of success is attributable to the process used for extraction, which does not expose the bark to long manipulations, and so preserves the quinine from the alteration.

The last objection is drawn from the constant presence of cinchonine in the cinchona barks, which not being completely insoluble in ether may involve some error. This is a more serious objection than the preceding. But at the most the cinchonine in the etherial solution can never exceed 0·45 per cent., and when yellow barks are operated on the error ought to be much less, because these barks ordinarily contain very little cinchonine.

If, however, because of the cinchonine, the method does not afford an absolutely correct valuation, it must be confessed that it gives a relative result in a manner more precise, more rapid, and more easily than any other process. A bark which shows 2·5, 3·0, or 3·4 per cent. is certainly and necessarily better, and will contain more quinine than that which shows only 1·0, or 1·2. Their experiments have proved to the authors that barks which yield 3·0 per cent. of quinine are rare in commerc, whilst those which give only 1·2 are abundant.

Adulteration of Rhubarb.[1]

In France as well as in England the powder of Turkey rhubarb it seems, is extensively adulterated with that of the home grown root. M. E. Billot gives a method for detecting this adulteration, which if successful, is certainly very simple. Place a little of the suspected rhubarb in a glass, or on a plate, and drop on it two or three drops of some essential oil, either bergamot, aniseed, or fennel, then add a little magnesia, and rub them together for three or four minutes. If the rhubarb be pure Turkey or Russian, the powder remains of a yellowish colour: but if it contain a mixture of French (Rheum rhaponticum) it assumes a tint which will vary from a salmon to the brightest rose-colour, according as there is little or much of the adulterating ingredient. We can by this means, says M. Billot, discover the least trace of fraud, and the test can be used by anybody, as it requires neither study, nor manipulatory skill.

[1] *Science pour Tous.*

The Comparative Value of different Species of Aconite.[1]

The various species of aconite, like the various species of cinchona, are known to contain different proportions of the active principle. The *aconitum paniculatum* is found to possess the least, and the *aconitum napellus* which resembles in all points, in its botanical characters as well as its energetic properties, the *aconitum ferox* of the Himalaya is found to yield the most aconitine.

The alcoholic extract furnished by an equal weight of fresh leaves of the two sorts differ notably. The *aconitum paniculatum* yields a third more product; but the extract of the aconitum napellus furnishes a considerable quantity of aconitine, while that of the paniculatum gives only a trace. The aqueous extract of the aconitum napellus is almost inert, the reason being that *tannate of aconitine*, which water alone will not dissolve, is formed in the marc during the preparation of the extract.

ROYAL INSTITUTION OF GREAT BRITAIN.

A Course of Six Lectures[1] *(adapted to a Juvenile Auditory), consisting of Illustrations of the Various Forces of Matter, i. e. of such as are called the Physical or Inorganic Forces — including an Account of their Relations to each other; by* M. Faraday, *D.C.L., F.R.S., Fullerian Professor of Chemistry, R.I., Foreign Associate of the Academy of Sciences, Paris, &c.*

Lecture V. (Jan. 6, 1860). *Magnetism—Electricity.*

I wonder whether we shall be too deep to-day or not. Remember, that we spoke of the attraction by gravitation of *all* bodies to all bodies by their simple approach. Remember, that we spoke of the attraction of particles of the *same* kind to each other,—that power which keeps them together in masses,—iron attracted to iron, brass to brass, or water to water. Remember, that we found, on looking into water, that there were particles of two different kinds attracted to each other; and this was a great step beyond the first simple attraction of gravitation; because here we deal with attraction between *different* kinds of matter. The hydrogen could attract the oxygen and reduce it to water, but it could not attract any of its own particles, so that there we obtained a first indication of the existence of *two* attractions.

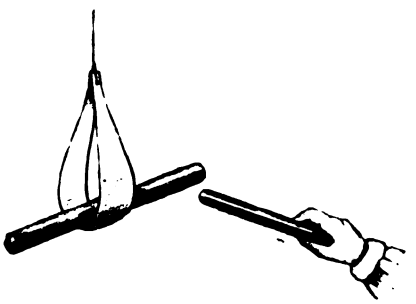
To-day we come to a kind of attraction even more curious than the last, namely, the attraction which we find to be of a double nature—of a curious and dual nature. And I want first of all to make the nature of this doubleness clear to you. Bodies are sometimes endowed with a wonderful attraction, which is not found in them in their ordinary state. For instance, here is a piece of shellac, having the attraction of gravitation, having the attraction of cohesion, and if I set fire to it, it would have the attraction of chemical affinity to the oxygen in the atmosphere. Now all these powers we find *in* it as if they were parts of its substance; but there is another property which I will try and make evident by means of this ball, this bubble of air [a light india-rubber ball, inflated and suspended by a thread]. There is no attraction between this ball and this shellac at present; there may be a little wind in the room slightly moving the ball about, but there is no attraction. But if I rub the shellac with a piece of flannel [rubbing the shellac, and then holding it near the ball], look at the attraction which has arisen out of the shellac, simply by this friction, and which I may take away as easily by drawing it gently through my hand. [The Lecturer repeated the experiment of exciting the shellac, and then removing the attractive power by drawing it through his hand.] Again you will see I can repeat this experiment with another substance; for if I take a glass rod and rub it with a piece of silk covered with what we call amalgam, look at the attraction which it has, how it draws the ball towards it; and then, as before, by quietly rubbing it through the hand, the attraction will be all removed again to come back by friction with this silk.

But now we come to another fact. I will take this piece of shellac, and make it attractive by friction; and remember that

[1] Reported verbatim by special permission.

whenever we get an attraction of gravity, chemical affinity, adhesion, or electricity (as in this case), the body which attracts is attracted also, and just as much as that ball was attracted by the shellac, the shellac was attracted by the ball. Now I will suspend this piece of excited shellac in a little paper stirrup, in this way, (*fig.* 1.) in order to make it move easily, and I will take another

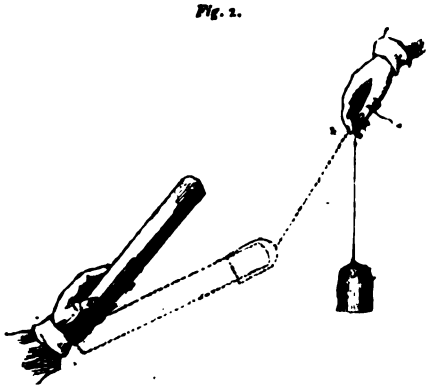
Fig. 1.



piece of shellac, and after rubbing it with flannel, will bring them near together: you will think that they ought to attract each other, but now what happens? It does not attract; on the contrary, it very strongly *repels*, and I can thus drive it round to any extent. These, therefore, repel each other, although they are so strongly attractive—repel each other to the extent of driving this heavy piece of shellac round and round in this way. But if I excite this piece of shellac as before, and take this piece of glass and rub it with silk and then bring them near, what think you will happen? [The Lecturer held the excited glass near the excited shellac, when they attracted each other strongly.] You see, therefore, what a difference there is between these two attractions,—they are actually two *kinds* of attraction concerned in this case, quite different to anything we have met with before; but the *force* is the same. We have here then a double attraction—a dual attraction or force—one attracting and the other repelling.

Again, to show you another experiment which will help to make this clear to you. Suppose I set up this rough indicator again [the excited shellac suspended in the stirrup]; it is rough, but delicate enough for my purpose; and suppose I take this other piece of shellac, and take away the power, which I can do by drawing it gently through the hand; and suppose I take a piece of flannel (*fig.* 2.) which I have shaped into a cap for it,

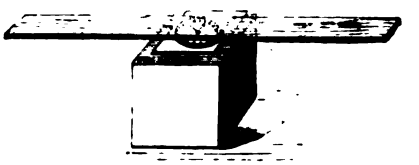
Fig. 2.



and made dry. I will put this shellac into the flannel, and here comes out a very beautiful result. I will rub this shellac and the flannel together (which I can do by twisting the shellac round), and leave them in contact; and then if, I ask, by bringing them near our indicator, what is the attractive force?—it is nothing! But if I take them apart, and then ask what will they do when they are separated,—why the shellac is strongly repelled, as it was before, but the cap is strongly attractive; and yet if I bring them both together again, there is no attraction—it has all disappeared [the experiment was repeated]. Those two bodies therefore still contain this attractive power—when they were parted it was evident to your senses that they had it, though they do not attract when they are together.

This then is sufficient in the outset to give you an idea of the nature of the force which we call ELECTRICITY. There is no end to the things from which you can evolve this power. When you go home take a stick of sealing-wax—I have rather a large stick, but a smaller one will do—and make an indicator of this sort (*fig.* 3.)

Fig. 3.



Take a watch glass (or your watch itself will do, you only want something which shall have a round face), and now if you place a piece of flat glass upon that, you have a very easily moved centre; and if I take this lath and put it on the flat glass (you see I am searching for the centre of gravity of this lath, I want to balance it upon the watch glass), it is very easily moved round, and if I take this piece of sealing-wax and rub it against my coat, and then try whether it is attractive [holding it near the lath], you see how strong the attraction is; I can even draw it about. Here then you have a very beautiful indicator, for I have with a small piece of sealing-wax and my coat pulled round a plank of that kind, so you need be in no want of indicators to discover the presence of this attraction. There is scarcely a substance which we may not use. Here are some indicators (*fig.* 4.) I bend round a strip of paper into a hoop and

Fig. 4.

we have as good an indicator as can be required; see how it rolls along, travelling after the sealing-wax. If I make them smaller, of course we have them running faster, and sometimes they are actually attracted up into the air. Here also is a little collodion balloon. It is so electrical that it will scarcely leave my hand unless to go to the other. See how curiously electrical it is; it is hardly possible for me to touch it without making it electrical; and here is a piece which clings to anything it is brought near, and which it is not easy to lay down. And here is another substance, gutta-percha, in thin strips; it is astonishing how by rubbing this in your hands you make it electrical; but our time forbids us to go further into this subject at present; you see clearly there are two kinds of electricities which may be obtained by rubbing shellac with flannel or glass with silk.

Now, there are some curious bodies in nature (of which I have two specimens on the table) which are called *magnets* or *loadstones*; ores of iron, of which there is a great deal sent from Sweden. They have the attraction of gravitation, and attraction of cohesion, and certain chemical attraction; but they also have a great attractive power, for this little key is held up by this stone. Now, that is not chemical attraction, it is not the attraction of chemical affinity, or of aggregation of particles, or of cohesion, or of electricity (for it will not attract this ball if I bring it near it), but it is a separate and dual attraction, and what is more, one which is not readily removed from the substance, for it has existed in it for ages and ages in the bowels of the earth. Now we can make artificial magnets (you will see me to-morrow make artificial magnets of extraordinary power). And let us take one of these artificial magnets, and examine it, and see where the power is in the mass, and whether it is a dual power. You see it attracts these keys, two or three in succession, and it will attract a very large piece of iron. That then is a very different thing indeed to what you saw in the case of the shellac, for *that* only attracted a light ball, but here I have several ounces of iron held up. And if we come to examine this attraction a little more closely, we shall find it presents some other remarkable differences; first of all, one end

of this bar (*fig.* 5.) attracts this key, but the middle does not attract. It is not then the *whole* of the substance which attracts. If I place this little key in the middle it does not adhere; but if I place it *there*, a little nearer the end, it does, though feebly. Is it not then very curious to find that there is an attractive power at the extremities which is not in the middle!—to have thus in one bar two places in which this force of attraction resides. If I take this bar and balance it carefully on a point, so that it will be free to move round, I can try what action this piece of iron has on it. Well, it attracts one end, and it also attracts the other end, just as you saw the shellac and the glass did, with the

Fig. 5.

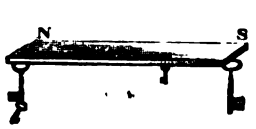


Fig. 6.

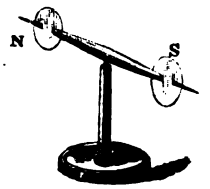


exception of its not attracting in the middle. But if now, instead of a piece of iron, I take a *magnet*, and examine it in a similiar way, you see that one of its ends *repels* the suspended magnet; the force then is no longer attraction but repulsion; but, if I take the other end of the magnet and bring it near, it shows attraction again.

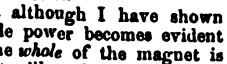
You will see this better, perhaps, by another kind of experiment. Here (*fig.* 6.) is a little magnet, and I have coloured the ends differently so that you may distinguish one from the other. Now this end (. . . .) of the magnet (*fig.* 5.) attracts the *uncoloured* of the little magnet. You see it pulls it towards it with great power. And as I carry it round, the uncoloured end still follows. But now if I gradually bring the middle of the bar magnet opposite the uncoloured end of the needle, it has no effect upon it, either of attraction or repulsion, until, as I come to the opposite extremity (. . . .) you see that it is the *coloured* end of the needle which is pulled towards it. We are now therefore dealing with two kinds of power, attracting different ends of the magnet—a double power, already existing in these bodies, which takes up the form of attraction and repulsion. And now when I put up this label with the word MAGNETISM, you will understand that it is to express this double power.

Now with this loadstone you may make magnets artificially. Here is an artificial magnet (*fig.* 7.) in which both ends have been brought together in order to increase the attraction. This mass will lift that lump of iron, and what is more, by placing this *keeper*, as it is called, on the top of the magnet, and taking hold of the handle it will adhere sufficiently strongly to allow itself to be lifted up, so wonderful is its power of attraction. If you take a needle, and just draw one of its ends along one extremity of the magnet, and then draw the other end along the other extremity, and then gently place it on the surface of some water (the needle will generally float on the surface, owing to the slight greasiness communicated to it by the fingers) you will be able to get all the phenomena of attraction and repulsion, by bringing another magnetised needle near to it.

Fig. 7.

I want you now to observe that although I have shown you in these magnets that this double power becomes evident principally at the extremities, yet the *whole* of the magnet is concerned in giving the power. That will at first seem rather strange, and I must therefore show you an experiment to prove that this is not an accidental matter, but that the whole of the mass is really concerned in this force, just as in falling the whole of the mass is acted upon by the force of gravitation. I have here (*fig.* 8.) a steel bar, and I am going to make it a magnet, by rubbing it on the large magnet (*fig.* 7.) I have now made the two ends magnetic in opposite ways. I do not at present know one from the other, but we can soon find out. You see when I bring it near our magnetic needle (*fig.* 6.) one end repels and the

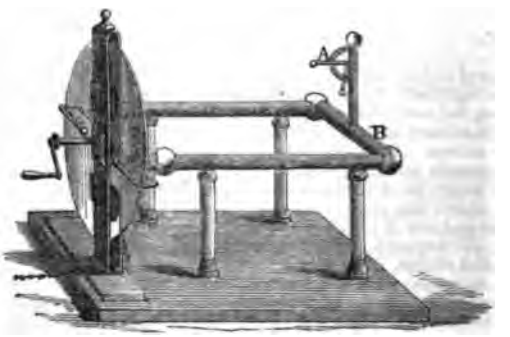
Fig. 8.



other attracts; and the middle will neither attract nor repel—it *cannot*, because it is *half way between the two ends*. But now, if I break out that piece (n. s.) and then examine it—see how strongly one end (n) pulls at this end (s *fig.* 6.) and how it repels the other end (N). And so it can be shown that every part of the magnet contains this power of attraction and repulsion, but that the power is only rendered evident at the end of the mass. You will understand all this in a little while, but what you have now to consider is that every part of this steel is in itself a magnet. Here is a little fragment which I have broken out of the very centre of the bar, and you will still see that one end is attractive and the other is repulsive. Now, is not this power a most wonderful thing? And very strange, the means of taking it from one substance and bringing it to other matters. I cannot make a piece of iron or anything else heavier or lighter than it is; its cohesive power it must and does have; but, as you have seen by these experiments, we can add or subtract this power of magnetism, and almost do as we like with it.

And now we will return for a short time to the subject treated of at the commencement of this lecture. You see here (*fig.* 9.)

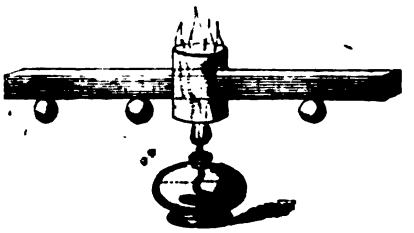
Fig. 9.



a large machine got up for the purpose of rubbing glass with silk and for obtaining the power called *electricity;* and the moment the handle of the machine is turned a certain amount of electricity is evolved, as you will see by the rise of the little straw indicator (. . . .) Now I know from the appearance of repulsion of the pith ball at the end of the straw that electricity is present in those brass conductors (. . .), and I want you to see the manner in which that electricity can pass away [touching the conductor (. . .) with his finger, the Lecturer drew a spark from it, and the straw electrometer immediately fell]. There, it has all gone; and that I have really taken it away you shall see by an experiment of this sort. If I hold this cylinder of brass by the glass handle and touch the conductor with it I take away a little of the electricity. You see the spark in which it passes, and observe that the pith ball indicator has fallen a little, which seems to imply that so much electricity is lost; but it is not lost, it is here in this brass, and I can take it away and carry it about, not because it has any substance of its own, but by some strange property which we have not before met with as belonging to any other force. Let us see whether we have it here or not. [The Lecturer brought the charged cylinder to a jet from which gas was issuing; the spark was seen to pass from the cylinder to the jet, but the gas did not light.] Ah! the gas did not light, but you saw the spark; there is perhaps some draught in the room which blew the gas on one side, or else it would light; we will try this experiment afterwards. You see from the spark that I can transfer the power from the machine to this cylinder, and then carry it away and give it to some other body. You know very well as a matter of experiment that we can transfer the power of heat from one thing to another; for if I put my hand near the fire it gets hot. I can show you this by placing before us this ball which has just been brought red-hot from the fire. If I press this wire to it some of the heat will be transferred from the ball, and I have only now to touch this piece of gun-cotton with the hot wire and you see how I can transfer the heat from the ball to the wire and from the wire to the cotton. So you see that some powers are transferable and others are not. Observe how long the heat stops in this ball. I might touch it with the wire, or with my finger, and if I did so quickly, I should merely burn the surface of the skin; whereas if I touch that cylinder however rapidly with my finger the electricity is gone at once—dispersed on the instant, in a manner wonderful to think of.

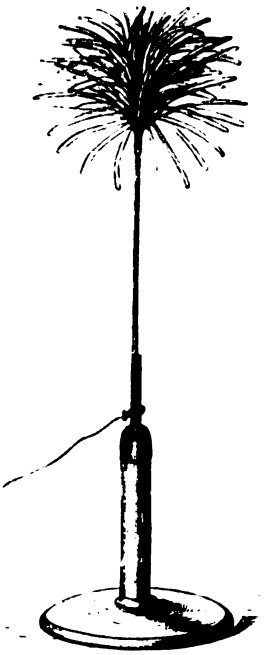
ust now take up a little of your time in shewing you the
er in which these powers are transferred from one thing to
er; for the manner in which *force* may be conducted or
nitted is extraordinary, and most essential for us to under-
. Let us see in what manner these powers travel from
to place. Both heat and electricity can be conducted; and
s an arrangement I have made to shew how the former can
. It consists of a bar of copper (*fig.* 10.) and if I take a

Fig. 10.



lamp (this is one way of obtaining the power of heat) and
t under that little chimney, the flame will strike against
: of copper and keep it hot. Now you are aware that
is being transferred from the flame of that lamp to the
and you will see by and by that it is being conducted
he copper from particle to particle; for, inasmuch as I
astened these wooden balls by a little wax at particular
es from the point where the copper is first heated, first
I will fall and then the more distant ones, as the heat
along, and thus you will learn that the heat travels
lly through the copper. You will see that this is a very
onduction of power as compared with electricity. If I
linders of wood and metal joined together at the ends and
piece of paper round and then apply the heat of this lamp
place where the metal and wood join, you will see how the
ll accumulate where the wood is, and burn the paper with
have covered it; but where the metal is beneath, the heat
ncted away too fast for the paper to be burned. And
ike a piece of wood and a piece of metal joined together,
it so that the flame shall play equally both upon one and
er, we shall soon find that the metal will become hot
ie wood; for if I put a piece of phosphorus on the wood,
ther piece on the copper, you will find that the phosphorus
opper will take fire before that on the wood is melted;
shows you how badly the wood conducts heat. But
ard to the travelling of electricity from place to place
ity is astonishing. I will, first of all, take these pieces
and metal, and you will soon understand how it is that
does not lose the power which it acquired when it is
by the silk; by one or two experiments I will show
I take this piece of brass and bring it near the ma-
ou see how the electricity leaves the latter and passes
ass cylinder. And again, if I take a rod of metal and
e machine with it I lower the indicator, but when I
with a rod of glass no power is drawn away, showing
t the electricity is conducted by the glass and the
a manner entirely different; and to make you see
e clearly we will take one of our Leyden jars. Now,
not embarrass your minds with this subject too much,
take a piece of metal and bring it against the knob
p and the metallic coating at the bottom you will see
ricity passing through the air as a brilliant spark. It
sensible time to pass through this, and if I were to take
etallic wire, no matter what the length, at least as far
concerned; and if I make one end of it touch the out-
the other touch the knob at the top—see how the
r passes!—it has flashed instantaneously through the
ngth of this wire. Is not this different from the trans-
f heat through this copper-bar, (*fig.* 10.) which has taken
of an hour or more to reach the first ball?
s another experiment, for the purpose of shewing the
ility of this power through some bodies and not through
Why do I have this arrangement made of brass?
: to the brass work of the electrical machine, *fig.* 9.]
t conducts electricity. And why do I have these columns
lass? Because they obstruct the passage of electricity.
do I put that paper tassel (*fig.* 11.) at the top of the
n a glass rod, and connect it with this machine by
a wire? You see at once that as soon as the handle of the machine is turned the electricity which is evolved travels along this wire and up the wooden rod, and goes to the tassel at the top, and you see the power of repulsion with which it has endowed these strips of paper, each spreading outwards to the ceiling and sides of the room. The outside of that wire is covered with gutta-percha; it would not serve to keep the force from you if you touched it with your hands, because it would burst through, but it answers our purpose for the present. And so you see how easily I can manage so as to send this power of electricity from place to place by choosing the materials which can conduct the power. Suppose I want to fire a portion of gunpowder, I can readily do it by this transferable power of electricity. I will take a Leyden jar, or any other arrangement which gives us this power, and arrange wires so that they may carry the power to the place I wish; and then placing a little gunpowder on the extremities of the wires, the moment I make the connexion by this discharging rod, I shall fire the gunpowder [the connexion was made and the gunpowder ignited]. And if I were to shew you a stool like this, and were to explain to you its construction, you could easily understand that we use glass legs because these are capable of preventing the electricity from going away to the earth. If, therefore, I were to stand on this stool and receive the electricity through this conductor I could give it to anything that I touched. [The Lecturer stood upon the insulating stool and placed himself in connection with the conductor of the machine.] Now I am electrified, I can feel my hair rising up as the paper tassel did just now. Let us see whether I can succeed in lighting gas by touching the jet with my finger. [The Lecturer brought his finger near a jet from which gas was issuing, when after one or two attempts the spark which came from his finger to the jet set fire to the gas.] You now see how it is that this power of electricity can be transferred from the matter in which it is generated, and conducted along wires and other bodies and thus be made to serve new purposes utterly unattainable by the powers we have spoken of on previous days; and you will not now be at a loss to bring this power of electricity into comparison with those which we have previously examined, and to-morrow we shall be able to go further into the consideration of these transferable powers.

Fig. 11.



(*The Sixth and last Lecture, on the* Correlation of the Physical Forces, *will be given in our next.*)

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY,—*Jan.* 19, 1860—*concluded.*

Professor Brodie, *F.R.S. President, in the Chair.*

Mr. Frederick Field made a verbal communication respecting the double sulphides of copper and iron. He observed that, from many analyses of those compounds, the sulphur, copper, and iron, existed in certain definite proportions, the copper being always in the state of disulphide (Cu_2S) whilst the iron appeared to be in many different states of sulphuration. By washing, or by the addition of carbonates or oxides of copper, the percentage of that metal was necessarily increased, a proportionately larger number of atoms of disulphide being formed to the atoms of the sulphides of iron, until by continuing the process still further all the iron was

expelled, and a simple di-sulphide of copper remained. Thus a regulus containing 17·20 of copper, was found likewise to contain 52·68 per cent. iron, and 30·10 sulphur, and the formula of this compound may be expressed by the following numbers:

$$(Cu_2S)\ Fe_2S_3,\ FeS,\ 2Fe_2S.$$

or one of disulphide of copper in union with one of sesquisulphide, one of protosulphide, and two of di-sulphide of iron.

On roasting the above for some time, the compound of

Cu	36·12
Fe	56·78
S	27·08
	99·98

was obtained, agreeing with the formula

$$3(Cu_2S),\ Fe_2S_3,\ FeS,\ 2Fe_2S$$

and by further similar treatment:

	Cu	49·71
	Fe	25·34
	S	24·85
		99·90
and	Cu	61·34
	Fe	15·65
	S	25·00

agreeing respectively to

$$6(Cu_2S)\ Fe_2S_3,\ FeS,\ 2Fe_2S.$$

and

$$12\ (Cu_2S)\ Fe_2,\ FeS_2,\ 2Fe_2S.$$

Mr. Field also remarked how greatly the increase of copper in regulus reduced the iron in comparison with the sulphur, thus in the last analysis, the sulphur is less by two per cent. than in the preceding, and the iron is 10 per cent., so that in practice not much advantage is gained, as far as the expulsion of sulphur is concerned, by calcining regulus of a per centage of 60 to 70 than of 45 to 50.

The same gentleman briefly explained two different modes of reducing regulus to powder, employed in some establishments in South America. One, by a process patented sometime since by Mr. Napier, which consisted in adding nitrate of soda to the regulus in the furnace immediately after skimming, and by plunging the *pigs*, after tapping, in a tank of water — the regulus was reduced to an impalpable powder, by the disintegration, and a sulphide of sodium formed, which dissolved out small quantities of the sulphides of antimony and arsenic. The other method consisted in simply crushing and sifting the regulus. Both methods have their attendant advantages, but whereas in the latter method regulus of any per centage may be crushed, that compound, in Mr. Napier's process, must not contain more than 50, or at any rate 54 per cent. of copper, or disintegration will not take place.

The Chairman, after Mr. Field had concluded his paper, called the attention of the meeting to a cast of a nugget of gold, kindly shown by Mr. Tennant. It came from King-over Diggings, 120 miles from Melbourne. It was melted in August, 1858, and yielded gold to the value of 690*l.* 12*s.* 9*d.*

Dr. Longstaff mentioned with reference to gold that some years since upon visiting some gold regions, there was one circumstance which came before him to which he paid particular attention at the time, and which ended in a practical result of considerable advantage to miners. It was found that, in extracting the gold from quartz, the yield varied very considerably, and at times they were much disappointed in the quantity of gold yielded by quartz from the same locality,— in fact, at one time they got a considerable product, and another time they procured very little from another batch of the same ore. That induced him to examine the material which was left after extraction, and on testing the *tail* he found a considerable quantity of gold in it, which however on bringing it in contact with quicksilver refused to amalgamate. That led him to suspect that there might be a coating of unctuous matter on the gold which prevented the action of the mercury. He suggested therefore that they should mix with the crushed quartz a quantity of wood ashes, and by that means they succeeded in very considerably increasing the yield. He proposed the working over again of 50 or 60 tons of *tailing*, which was accordingly done, and they got very much larger quantities of gold from it than they did from the original ore. He thought that in all cases where wood ashes could be obtained without much difficulty it would be found advisable to add them from time to time in the mills. In the case just mentioned it was thought a most wonderful discovery, and was the means of causing some mills to be reworked at a profit which had before been obliged to stop.

Mr. Field stated that he had had some large pieces of so-called native zinc sent to him for analysis. They were almost entirely soluble in dilute sulphuric acid. On speaking to one of the workmen about them he was shown how this native zinc was formed. The miners worked up clay into a hollow lump and then poured melted zinc into it. This was afterwards rubbed over with earth, which gave it the appearance of silver stone. Travellers passing by the mines would readily purchase these specimens.

Mr. Phillips stated that wood ashes had been found to be of very great use in the barrel amalgamation process of extracting silver in Spain. It seemed to assist the process in some way or other — perhaps in the way suggested as to gold.

UNIVERSITY OF LONDON.

The Senate of this University has recently, in accordance with representations made to it by many of the most eminent men of science in the country, instituted the degrees of *Bachelor* and *Doctor of Science* (B. Sc. and D. Sc.). Candidates for the former degree, that of B. Sc., will be required to have passed the matriculation examination, and to pass two subsequent examinations: but Bachelors of Arts of this university, and undergraduates who shall have passed the first examination for the degree of Bachelor of Medicine of this university, will be admitted to the degree of Bachelor of Science on passing the second B. Sc. examination only.

The first B. Sc. examination is to take place once a year, and to commence on the third Monday in July. No candidate will be admitted to this examination within one academical year of the time of his passing the matriculation examination, nor unless he has transmitted to the registrar, at least a month before the commencement of the examination, a satisfactory certificate of good conduct.

The fee for the examination will be 5*l.*; and candidates will not be approved unless they show a competent knowledge of the fundamental principles of (1.) Mathematics; (2.) Mechanical and Natural Philosophy; (3.) Chemistry; (4.) Biology, including Botany and Vegetable Physiology, and Zoology and Animal Physiology.

Any candidate who has passed the first B. Sc. examination may be examined for honours.

The second B. Sc. examination will take place once a year, and will commence on the fourth Monday in October. No candidate will be admitted to it within one academical year of the time of his passing the first B. Sc. examination. The fee and the regulation with regard to the certificate of good conduct are the same as in the former case. The subjects of examination will be, Mechanical and Natural Philosophy, — Chemistry, Inorganic and Organic, Theoretical and Practical, — Animal Physiology, — Geology and Palæontology, — Logic, and Moral Philosophy.

Any candidate who has passed may be examined for honours.

The examination for the degree of Doctor of Science (D. Sc.) is to take place annually within the first fourteen days of June. No candidate will be admitted to this examination until after the expiration of two academical years from the time of his obtaining the degree of B. Sc. Candidates for this degree in any year must give notice of their intention to the registrar, and pay to him a fee of 10*l.* on or before the 1st of April.

The subjects embrace the usual branches of Physical, Biological, Geological, and Mental Science.

In following the course of study required as a preparation for these degrees, candidates are left to their own free choice both as to locality and as to instructors; and by the new charter recently granted to the university, candidates for the degrees in *Arts* enjoy the same liberty, so that these degrees also are now open to every one who can stand the test of the successive examinations to which candidates for them are subjected.

NOTICES OF BOOKS, PATENTS, &c.

The Radical Theory in Chemistry, by JOHN JOSEPH GRIFFIN, *F.C.S., Hon. Member of the Philosophical Society of Glasgow.* 1858. London: J. J. Griffin, Bunhill Row.
Chemical Recreation: a popular Manual of Experimental Chemistry. Same Author. Tenth Edition. 1860.

THERE are more than one kind of chemists. There are the real workers in the science, men who spend the best part of their lives in the laboratory, earnestly accumulating facts; men whose greatest happiness is the production of new substances; men who use the theories in vogue merely as means to an end, who have a certain amount of faith in them, but who do not care one iota whether oxygen has an atomic weight of eight or sixteen, or whether an atom of hydrogen occupies the same or twice the space of oxygen. Such men know that the quantities in chemistry are merely relative — that we have no means as yet of knowing the absolute truth as it exists in the mind of the Deity — and they are satisfied with receiving chemical theories more as systems of classification than as expressions of ultimate fact. There are others who consider these points as vital, who will descant with great ingenuity, but less temper, not only upon the impossibility of more than one system of chemical notation being correct, but also upon the utter stupidity of all who do receive the one system with implicit faith. These second class of chemists do not, as a general rule, make researches, — they read the researches of others, and, while reading, slowly but solemnly inflate, the principle of expansion being a sublime consciousness of the inferiority of the worker to the theorizer. Sir Humphry Davy has said: "When I consider the variety of theories which may be formed on the slender foundation of one or two facts, I am convinced that that it is the business of the true philosopher to avoid them altogether. It is more laborious to accumulate facts than to reason concerning them; but one good experiment is of more value than the ingenuity of a brain like Newton's." There are facts — stern, unbending and uncompromising facts — which no theories now known will either reconcile or explain. There is not one theory which can explain the annexed equation.

$$C_4H_5Na + 2CO_2 = C_6H_5NaO_4.$$

It is a mere case of simple addition, and yet if any chemist had predicted such a synthesis he would have been pronounced insane. If chemists would always be honest enough to admit when the facts are first discovered and the theories drawn from them afterwards, how much better we should esteem them. The general rule is, as soon as a remarkable and probably unexpected fact comes to light, for the discoverer to write his paper as if he had foreseen the new reaction. If chemists did but know how internal evidence generally betrays their mental process, they would see the true policy of being strictly candid. We disclaim allusion to any one person or reaction, we allude to working chemists generally, here and abroad; and it is evidently impossible, for obvious reasons, that the remark we have made can apply to the author now mentioned.

Mr. J. J. Griffin has been for many years before the public both as an author and a commercial man. Chemists are not generally aware of the debt of gratitude they owe him for the introduction of foreign apparatus and appliances into this country. At a time when good chemicals and instruments were to the last degree difficult to procure, Mr. Griffin, at great pecuniary risk, brought from various parts of the continent to this country all that was likely to assist the working chemist in his labours. He also found time to make an excellent translation of Rose's *Treatise on Analysis*; he even produced a laborious work on Crystallography, and two other books, namely, the *Romance of Chemistry* and the *Chemical Recreations*. All these works display talent and powers of application of a superior kind. A more charming book for young students of chemistry than the first few editions of the *Chemical Recreations* was never penned. The *Romance of Chemistry*, although cleverly written, was deformed, like all his theoretical writings, by an unbecoming way of speaking of all who did not think in the same manner as himself. Even Berzelius, the profound, the laborious Berzelius, whose memory all chemists who know the history of their science gratefully revere, was treated with a flippant ridicule which we should be sorry to apply even to the theories of our author.

The Radical Theory in Chemistry is a laboriously thoughtful book; it is not our intention to criticise the theories in it minutely in this place, because it would be utterly impossible in the space which can be spared to a review. It is the less necessary, because, in all probability, all that is original in them will before long be noticed in Dr. Odling's work. We may however mention that the author appears to consider ridicule as powerful an engine of conversion as he did a quarter of a century ago. At page 201 he says: "I shall, for the sake of brevity, only quote such of these names," alluding to the organic bases, "as serve either to identify the compounds, or to exhibit some of the vagaries of chemists, or to illustrate important or disputed doctrines." Mr. Griffin is ironical in his remarks on Dr. Hofmann's systematic but necessarily sesquipedalian nomenclature for the bases discovered by him. He does not appear to be aware that Dr. Hofmann never intended these names to remain in science, but merely used them as a means of description. It is amusing, therefore, to find that Mr. Griffin seriously proposes to chemists to call dolomite, "bis magnen carbite tris calcen carbite," and to use such delightful terms as "zincen carbite cum zincabon hydronose" (p. 185).

Mr. Griffin is angry with Dumas for being sarcastic upon Longchamp, but he nevertheless hurls the following avalanche of irony upon M. Stadeler, and his base acetonine:—"I do not believe in the existence of this assumed new base. Acetone itself contains acetyl and methyl, see p. 77. Acetonia is comprised of an ammon and an amid, including the same radicals; and the platinum salt and the binoxalate can be explained (see Nos. 205, 206) without resorting to the expedient of creating a hypothetical 'new base' to meet the special circumstances, an expedient to which organic chemists resort with a too ready facility. When compound salts can be clearly explained by means of well-known existing radicals, what is the use of making imaginary bases? In the present case, three atoms of methyl, three atoms of acetyl, and two atoms of azote are rolled up into a giant new base, and called acetonia. This method of practising synthesis is becoming really alarming" (p. 216). After this we may consider M. Stadeler and his unhappy base as having ceased to exist.

Mr. Griffin generally writes in a tone indicative of extreme mental depression, but at p. 292 he recklessly plunges into the funny.

"The name melaniline was adopted in consequence of a relationship or an analogy which Dr. Hofmann supposed to exist between this body and the compound which is usually called melamine. According to my way of formulating these two compounds, they are as follows:—

Melamine = ZH_2, Cyl = Amida cyanyla.

Melaniline = { ZH, C_6H_5; Cy } = Phenylac cyana cnm
{ ZH, C_6H_5; H } = phenyl hydra.

The relationship which exists between these two compounds is certainly very distant; a sort of Scotch-cousinship a great many times removed."

We wonder if Dr. Hofmann has ever read the work before us, and, if he has, how he felt on seeing the havoc which Mr. Griffin makes with his formulæ.

Every one remembers poor Laurent's exclamation, — "What have I to do with your copulæ, your radicals, and your castles of cards?" Mr. Griffin appears to endeavour to feebly imitate his style in many places, among others at p. 296, where, alluding again to his old enemy melaniline, he says: —

"What have we to do with mellon or aniline mellon, or with C_6H_4, or $C_{12}H_4$, or $C_{12}H_4N_4$? The process and its interpretation are extremely simple, and require none of these far-fetched luminaries to enlighten them."

Again, on the next page, we have —

"These three formulæ exhibit the usual excellencies of Gerhardt's 'type ammonia,' and make simple things complex with remarkable facility."

When we know that hundreds of chemists have found the types of the late illustrious chemist M. Gerhardt of the greatest assistance to them in their studies and researches, and that they have not as yet found the "Phenylam phenylac cyanen" of Mr. Griffin help them (at least except so far as it has contributed to give an air of playfulness to an otherwise grave subject), we cannot escape the conclusion that it would be better to avoid such attempts at sarcasm and fine writing.

At p. 308, chemists (by the way, it is evident from the perpetual abuse Mr. Griffin lavishes upon "chemists" that he does not consider himself to belong to the fraternity) are said to be in a "muddle" as regards the platinum bases. Undoubtedly there are great difficulties in the way of a clear understanding of the matter, and when we remember that Mr. Griffin repeats the classic word "muddle" no less than six times on p. 308, we *do* think he was bound to throw a new light upon it. He does not, however appear to agree with us upon this point.

At p. 313 Mr. Griffin, finding his subject a little too heavy even for him, plunges headlong into *The Renowned History of the Seven Champions of Christendom*. He then tells chemists to "unmuzzle their wisdom" (p. 314). We here anxiously ask if Mr. Griffin has been unmuzzled; because, if so, it is high time for "orthodox chemists" to look out.

We refrain, as an unprofitable task, from quoting any more of Mr. Griffin's sarcasms, or playful remarks; it is true that in one place he quotes Joe Miller, and that in another Mr. Woodin and Miss P. Horton are dragged in as illustrations; but as it appears to make him happy and does no one any harm, it may be passed over without further comment.

There can be no doubt that Mr. Griffin has most laboriously studied his subject, and that in many cases there is reason in his arguments. It is true that he is not always careful to let us know exactly the amount of novelty in his views, that he does not always tells us whose ideas he is enunciating, and therefore the student may sometimes give him a little more praise for originality than he deserves; but it may in fairness be set off against the numerous instances where arguments which are strictly his own will pass without obtaining a proper meed of appreciation.

There is one important point upon which our author insists very strongly, and where he has a certain amount of common sense on his side. As usual, however, he deforms his argument by a melancholy attempt at sarcastic writing. We allude to the use of hydrogen as a standard for the specific gravities of gases and vapours. At p. 140 of his *Chemical Recreations*, he says: —

"One of the marvels of modern chemistry is the persistence of its professors in the practice of comparing the specific gravities of gases with that of common air taken as unity. To be consistent they should adopt the additional absurdity of taking the composition of common air as the standard of the atomic weight. Just look at these two examples of specific gravities! the atomic weight of mercaptan is 62, and its specific gravity is 31; the atomic weight of alcohol is 46, and its specific gravity is 23; these numbers are too simple to have the proper look of philosophical profundity, so the authorities of our science fix the specific gravity of mercaptan at 2·15822, and of alcohol at 1·60049— beautiful numbers! which contain the quantity of Egyptian darkness necessary to render them grand and mysterious, and which confer upon the scientific world the remarkable advantages that always flow from the statement of simple facts in terms which no memory can retain."

Mr. Griffin does not appear to be aware that the adoption of hydrogen as the standard for specific gravities of gases and vapours is by no means a new idea. Faraday many years ago referred the densities of his oil gas hydrocarbons to hydrogen. Turner also published tables where the densities were referred to hydrogen as unity. These are only two examples out of many. Besides, every chemist knows quite well that it is only necessary to perform a sum in simple division, to convert the density as compared with air into the density as compared with hydrogen. Can it be possible that Mr. Griffin does not know the reason why chemists always publish their densities as compared with air! Does he not know that chemists, for obvious reasons, always weigh their balloons full of air before filling them with the gas or vapour to be compared with it? Chemists, therefore, are simply guilty of the crime of stating their results as they get them, and leaving ingenious theorists like Mr. Griffin to perform their problems in simple division for themselves.

To sum up, the new edition of *Chemical Recreations* is a handsome volume, illustrated with 537 cuts. It is useful as containing excellent views of the best modern apparatus. Descriptions of the facts of the science are almost always given in a clear comprehensive style. Mr. Griffin's own admirable blast gas furnace is clearly described in it, as well as the furnaces of Deville and others. A vast number of appliances are to be found in this work, which have never before appeared in a chemical treatise; and the absence (in most cases) of the insulting sarcasms which appear in almost every chapter of the *Radical Theory*, makes it a pleasant and readable book, and one which may with advantage be placed in the hands of students.

Improvements in Vulcanising and Colouring Caoutchouc, and in the preparation of Caoutchouc Paints and Colours. R. Archibald Brooman. 1859. A communication.

The process for vulcanising caoutchouc consists in passing it three or four times, at intervals of a day, through a bath prepared of benzine, having in solution 5 per cent. of red or black sulphuret of mercury, or 2 per cent. of bromide of sulphur. It is next immersed in a chloride of lime bath, containing about four pounds of chloride of lime to eight quarts of water, and allowed to remain there about twelve hours. It is then dried by exposing it for about eight days to a temperature of 60° or 70° Fahr.

In order to colour caoutchouc a portion is first dissolved in benzine, turpentine, olive oil or other solvent, and to produce the colours the following ingredients are used. For white, zinc white; for blue, ultramarine; for red, vermillion; for light brown, orpiment; for chocolate, a mixture of ultramarine and vermilion; for green, a mixture of ultramarine and chrome yellow.

Before other colours are applied to sheets of india-rubber it must be covered with two coats of zinc white, applied at intervals of about twenty-four hours, and upon this foundation the desired colours may be produced by the application of from three to five coats of the colour required. After the desired number of coats have been applied, the sheets in their extended state must be kept for six or eight days at a temperature of from 60° to 70° Fahr.

The inventor also makes elastic paints by mixing with ordinary paints India-rubber or gutta-percha dissolved in benzine, turpentine, olive, poppy, or linseed oils.

The caoutchouc paints or colours may be used for paintings or frescoes, for decorative purposes generally, for preserving buildings, and for protecting iron and other metals from oxidation.

CORRESPONDENCE.

The Atomic Theory.

To the Editor of the CHEMICAL NEWS.

SIR,—I beg leave to lay before you a proof of the existence of *indivisible atoms* that has lately occurred to me.

Let g represent the force of gravity upon the surface of a sphere whose radius is r, then $g \propto r^{-2}$ expresses the fact that gravity varies inversely as the square of the distance. Again, $g \propto r^{3}$ expresses the fact that gravity varies as the mass.

Hence we see that g varies conjointly as r^{-2} and r^{3}, therefore, $g \propto r^{-2} \times r^{3}$ and finally, $g \propto r$. So that we may say that the attraction between spheres vary as their radii. Now supposing that matter were *infinitely* divisible, we should have $r = 0$. But $g \propto r$, consequently the particles of which matter consists would have no attraction one for another, which is absurd, *therefore there are indivisible atoms.*—*J. S. Barrett.*

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

A New Reducing Agent. — The proto-sulphate of iron alone does not reduce either the bichloride of platinum or bichloride of mercury. M. Hempel [1] has remarked that the reduction is promptly effected when an alkali is added to the mixture. On treating bichloride of mercury by a mixture of protosulphate of iron and an alkali, and then adding sulphuric acid, protochloride of mercury is obtained. The filtered liquid is quite free from the metal. The nitrate and sulphate of mercury behave in the same way if care be taken to add previously a little chloride of sodium.

The author makes use of this reaction for the estimation of mercury. If the liquid contains at the same time gold and silver, these metals are precipitated beforehand, the one by means of proto-sulphate of iron, the other by chloride of sodium.

Preparation of Platinum Black. — M. Hempel [2] obtains platinum black by adding to bichloride of platinum, first protosulphate of iron, then caustic soda, and afterwards hydrochloric acid. The black powder which remains is well washed with acidulated water, and then dried.

The formation of metallic platinum is based on the reaction effected by the protoxide of iron.

Solubility of Tartrate of Baryta. — H. H. Vogel Reischauer [3] have observed that tartrate of baryta exists in two different states,—the amorphous and the crystalline; and that in the amorphous state the salt only requires 833 parts of water for solution, while in the crystalline state it requires 1300 parts. This difference in the solubility is shown by a very simple experiment. A precipitate of the amorphous tartrate being obtained, just sufficient water is added to redissolve it; in a few seconds the clear liquid becomes cloudy in consequence of the formation of crystalline tartrate.

Action of Chlorine on the Carbonates of Lime and Baryta. — M. Merz [4] passed chlorine gas at the ordinary temperature into water holding in suspension recently precipitated carbonates of baryta and lime. The chlorine was rapidly absorbed. When the operation was terminated the resulting solution was evaporated, and the residue was found to be composed of a mixture of the chlorates of baryta and lime as well as the chlorides of barium and calcium.

II. ORGANIC CHEMISTRY.

New Derivatives from Quercitrine. — Rigaud had found that quercitrine belonged to the glucosides, and might be decomposed into a carbohydrate and another body which he called *quercetine*. Hlasiwetz [5] has now found that quercetine itself contains the elements of a sugar, the *phloroglucine*, which the same chemist has observed among the products of the decomposition of phloretine. Quercetine is boiled with concentrated solution of potash, and is then diluted with water. The solution is now neutralised with hydrochloric acid, and after some time it deposits a flocculent matter formed of a mixture of quercetine, and an unstable body which appears to be a derivative of this principle. The liquid filtered from the flocculent matter is evaporated to dryness and then extracted with alcohol: the alcohol is then driven off and the residue dissolved in water. The solution now contains two substances separable by means of acetate of lead, which will not precipitate the phloroglucine. To isolate this the lead is removed from the filtered liquid by sulphuretted hydrogen, and the solution filtered from the sulphide of lead is quickly evaporated. Crystals of phloroglucine are deposited, which may be purified by animal charcoal.

The body precipitated by acetate of lead is a weak acid which offers some resemblance to gallic acid. The author gives it the name of quercetic acid. To obtain it the lead precipitate is decomposed by sulphuretted hydrogen, and the liquid filtered from the sulphide is carefully evaporated, on which brown crystals are formed which may be purified by animal charcoal.

When pure the crystals are silky needles slightly soluble in cold, but freely soluble in hot, water, in alcohol, and in ether. The aqueous solution becomes coloured in the air. The crystals are efflorescent and may be partially volatilised. Their solution reduces the salts of silver; perchloride of iron colours it black. When a few drops of an alkaline solution are added to a very dilute solution of quercetic acid it first turns yellow, and when agitated in the air becomes a beautiful red. The same acid colours strong sulphuric acid red, and water then separates red flakes which in contact with alkalies become of a magnificent purple.

In a crystalline state quercetic acid has the composition $C_{24}H_{12}O, 6 + 7HO$.

Ellagic acid, which a good deal resembles this acid, differs only by C_6H_6.

III. CHEMICAL ANALYSIS.

The Determination of Free and Combined Carbonic Acid and Sulphuretted Hydrogen in Mineral Waters. — The process suggested by M. Gaultier de Claubry [6] for determining the amount of free carbonic acid, apart from that which is combined with lime, magnesia, and protoxide of iron, in the form of soluble bicarbonates, consists in passing through the water either a current of atmospheric air which has been freed from carbonic acid, or a current of hydrogen. The free carbonic acid only is removed, and the bicarbonates remain in solution. When the water contains bicarbonate of iron hydrogen must be used, and the current of gas must be stopped the moment the liquid becomes cloudy, indicating the commencement of decomposition. The air or hydrogen, after passing through the water, is dried, and then passed through a weighed potash bulb.

Sulphuretted hydrogen in solution is equally well removed by a current of hydrogen which may be passed into a proper absorbing apparatus.

Chemical Composition of Meteorites.—Reichenbach[7] has collected together the analyses of a great number of meteorites; and taking into account only those which appear to him to be exact, and which relate to meteorites the fall of which has been well authenticated, he has found that the mean composition of these bodies in round numbers is as follows:—

Silica	40·00	Chromium	0·50
Magnesia	20·00	Manganese	0·33
Iron	25·00	Soda	0·33
Alumina	2·00	Other Elements	1·34
Sulphur	2·00	Oxygen	5·50
Lime	1·50		
Nickel	1·50		100·00

SCIENTIFIC NOTES AND QUERIES.

Determination of the amount of Alcohol in Wines or other alcoholic Fluids.—Sir,—The method given in the Chemical News (No. 3, p. 36) for determining the amount of alcohol in wines is not correct. In the first place there is an error in the working of the example; ·9873 is not the difference between 1·0080 and 0·9953; the difference is ·0127. But even were the rule followed it would give a false result, as will appear from the following:—The wine may be regarded as a mixture of two fluids A and B; A being a solution of sugar, tartar, &c., B a solution of alcohol in water. Let v_1, s_1 be the volume and specific gravity of A; v_2, s_2 the volume and specific gravity of B; then the specific gravity w_1 of the wine is $w_1 = \frac{v_1 s_1 + v_2 s_2}{v_1 + v_2}$. Now when B has been evaporated off and replaced by an equal volume v_2 of water of specific gravity = 1 the specific gravity w_2 of the mixture is $w_2 = \frac{v_1 s_1 + v_2}{v_1 + v_2}$. Taking the difference Δ, we get $\Delta = w_2 - w_1 = \frac{v_2(1 - s_2)}{v_1 + v_2}$. If *half* the wine is evaporated $v_1 = v_2$ ∴ in this case $\Delta = \frac{1 - s_2}{2}$ ∴ $s_2 = 1 - 2\Delta$. Hence in the example given we have $s_2 = 0{\cdot}9746$.—*E. G.*

Purification of Water by the use of Oxide of Manganese.—Sir,—Mr. Spencer appears to be rather *sharp* upon others respecting what he calls "his discovery." His own remark in your 4th number upon Professor Kuhlmann's paper, also applies to *himself*, viz.: "It is impossible for me to know what *private laboratory notes* do exist" now-a-day. In my opinion Mr. S. *assumes* rather too much for himself in regard to this question, and I doubt if his patent will *hold good*, and most certainly not as regards the use of *manganese*, which book after book *for years back* alludes to for purifying and sweetening water, and it is now several years since that its *decolorising* properties were brought to my notice. The law of patents requires *reform*. Some years ago I had to restrain a certain Liverpool chemist for *infringement* of a patent for purifying water which I had taken out a *dozen years* before and had sold to a French engineer; so that if this chemist's patent agent had done his duty, he would have prevented him from throwing away his money upon a *supposed priority* of invention, and running the risk of an "action of law." Mr. S. has entirely *misunderstood* that part of my letter which spoke of the admixture of chloride of lime with manganese. It was *not* intended to be applied to water for *household purposes*, but as a deodorant and disinfectant of liquid sewage, &c.—*John Horsley, F.C.S.*

[We do not think that a continuance of this discussion will either interest or instruct our readers.—Ed.]

The Metallic-iron Water-purifying Patent.—Sir,—In a short note which appeared in your third number, I remarked that the principle of the "purification of water by means of *metallic* iron" had been patented, but did not name the patentee. As the omission however has been taken advantage of, I think it right to state that Dr. Medlock is that gentleman, whose interesting researches were published in the *Philosophical Magazine* of September 1857 and January 1858.—*Thomas Salter, F.C.S.*

Stannate of Soda.—Sir,—Can any of your correspondents be good enough to furnish me with the practical process involved in the manufacture of *commercial* "*Stannate of Soda*," and oblige *A Subscriber.*

[7] *Poggendorf, Ann. der Physik und Chemie*, v. cvii. p. 553.

LABORATORY MEMORANDA.

Estimation of Mixtures of Acids or Alkalies in Solution.—The following method of analysing a mixture of acids or alkalies may be useful to some of your readers. The method will be explained most shortly by an example. Suppose then it were required to analyse a mixture of tartaric and citric acids; suppose w grains of the mixture contains x grains of tartaric and y grains of citric acid. Saturate w grains of the mixture with potass, and let w_1 = the number of grains of potass used. Again, saturate another w grains of the mixture with soda, and let w_2 = the number of grains of soda used. We then get two equations each containing the unknown quantities x and y, which may ∴ be found. The result is checked by saturating a third quantity of w grains with some other alkali; calling w the quantity of it used, we get another determination of x and y. If there were three acids in the mixture we should require three equations in order to determine the quantities of each. In general we require as many independent equations between the unknown quantities as there are unknown quantities.

The quantities of alkalies used for saturation are known at once, if we saturate with solutions of known strength, and deliver them from an alkalimeter.—*E. G.*

MISCELLANEOUS.

Effects of Arsenical Paper.—There is an exceedingly beautiful paper of an apple-green colour, which is often selected for the coolness and cheerfulness of its appearance. The writer was himself once deluded by the seductive appearance of a paper of this description, and had his library furnished with it. Strange to say, a violent cold seemed to seize every one, even in the midst of summer, who stopped long in this apartment, especially if they came much in contact with the walls. On questioning the paper-hanger, the mystery was speedily explained. "I never hang that kind of paper," he said "without getting a bad sore throat and a running of the eyes—all the trade knows it is good for a cold to have any dealings with it." The cheerful green of the paper is nothing less deadly than the aceto-arsenite of copper: an irritant poison of the first class. The flock of this paper contains a large quantity of pigment, in the form of dust, which is of course liable to be detached from the walls on very slight occasions. It has been erroneously supposed that the metal must be volatilised by heat ere it can be separated from the paper; but the action of detachment is mechanical and not chemical; the poisonous dust either falls or is brushed off the walls, and becomes mixed with the ordinary dust of the room; the lifting of a book, or the displacement of a pile of papers, proves sufficient to set these particles in motion, and to bring them into contact with the mucous membranes of the eyes, nose, and throat; hence the violent irritation produced, which simulates so closely the effects of a bad cold in the head.—*Edinburgh Review.*

Alum Lozenges.—A Venetian physician, Dr. Argenti, proposes to employ alum lozenges instead of alum gargles for sore throats, loss of voice, &c. He directs them to be prepared of alum, gum arabic, sugar and laurel water in such proportions that a lozenge of six grains may contain one grain of alum.

ANSWERS TO CORRESPONDENTS.

Mr. C.—The proportions vary according to the price and the consciences of the manufacturers. No two houses use the same proportion. No analyses of the kind have been published that we remember.

C. D. S.—We will comply with the wish of our correspondent soon.

W. H. (Tillydesk)—Next week.

W. M. (Manchester).—1. Sulphide of iron, which may be obtained at most chemists, would no doubt answer the purpose, if pyrites cannot be procured. 2. The simplest way is to burn it, and see the amount of ash left; ivory black leaves a great deal and charcoal scarcely any ash.

A. B. should consult an elementary work on chemistry.

X. Z.—The process does not answer on a large scale.

M. (Newcastle).—Either will answer.

G. C.—Impossible to advise.

A Subscriber (Leeds)—*Yokels*—*J. C. B.*—*De Monti*—received. Answers next week.

THE CHEMICAL NEWS.

VOL. I. No. 10. — February 11, 1860.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Chemical Polarisation of Neutral Oxygen which takes place with the slow combustion of Phosphorus, by C. F. SCHÖNBEIN.[1]

THE author first describes the behaviour of a mixture of aqueous phosphorous acid and peroxide of hydrogen. This mixture has the following reactions: —

1. A dilute solution of chromic acid containing only one per cent. of the acid, is first coloured blue by the mixture; but ordinary oxygen is soon developed, and the solution becomes permanently green in consequence of the formation of a salt of chrome oxide. Diluted phosphorous acid will not alone reduce the free chromic acid, because from a mixture of two acid solutions no oxygen can be set free.

2. The mixture instantaneously decolorises a solution of permanganic acid or permanganate of potash with the rapid development of ordinary oxygen and the formation of a salt of manganous oxide. It is true that pure diluted phosphorous acid will also reduce permanganic acid to manganous oxide, but slowly, and naturally without setting free oxygen gas.

3. With peroxide of lead the mixture developes ordinary oxygen in the formation of a salt of protoxide of lead.

4. The mixture when added to water will not by itself colour blue a dilute solution of iodide of potassium and starch (the concentrated mixture will do so); but on the addition of a few drops of a dilute solution of sulphate of iron the starch mixture is instantaneously coloured blue.

5. At the ordinary temperature the mixture will slowly decolorise a moderately strong solution of indigo; but on adding a few drops of sulphate of iron solution it is instantly decolorised.

6. The mixture may be kept at a temperature of 212° Fahr. for some hours without losing the power of turning the solution of iodide of potassium and starch blue, with the co-operation of the dilute sulphate of iron solution.

8. Platinum black placed in contact with the mixture occasions no perceptible development of oxygen gas; but by continued agitation of the metallic powder with the liquid, the power of turning the iodide of potassium paste blue is completely lost.

8. The mixture may remain for days in contact with finely divided phosphorus without losing the property of colouring the iodide of potassium paste blue; but by standing together a longer time the power is lost.

Let us now see how the acid liquid behaves which is obtained by the action of phosphorus on moist air, or oxygen attenuated by means of the air pump, and in which chemists until now have found nothing but phosphorus and a little phosphoric acid.

If some pieces of phosphorus an inch long, with a clean surface, are placed in an open porcelain dish with sufficient water to about half cover them, and are allowed to remain for 18 or 24 hours at a temperature of from 60° to 68° Fahr., the acid liquid which is poured away from the phosphorus will show the following reactions:

1. On mixing the liquid with dilute chromic acid solution, it is at first coloured somewhat blue; but if the phosphorus has been exposed to the action of the atmospheric oxygen a sufficient time, and provided too much chromic acid has not been used, the solution becomes of a permanent green colour, owing to the formation of a salt of chrome oxide, as is evident from the circumstance that chrome oxide may be precipitated from the green solution.

2. A solution of permanganic acid or permanganate of potash is instantaneously decolorised by the liquid, by the development of ordinary oxygen and the formation of a salt of manganous oxide.

3. Placed in contact with peroxide of lead the liquid sets free ordinary oxygen from the formation of a salt of lead oxide.

4. The strong liquid diluted with water loses the power of turning the iodide of potassium and starch solution blue by itself, (the concentrated solution will do this,) but on the addition of a few drops of a solution of sulphate of iron the mixture instantly acquires the deepest blue colour.

5. If coloured blue with indigo tincture, the mixture is slowly decolorised at the ordinary temperature, but it is changed instantly on the addition of a dilute solution of sulphate of iron.

6. The mixture may be kept boiling for some hours (being brought up to its original bulk by occasional additions of water) without losing the power of changing the iodide of potassium and starch solution blue with the help of the sulphate of iron.

7. Platinum black introduced into the liquid occasions no sensible evolution of oxygen gas, but if the two be shaken together for some time the liquid loses the power of bluing the iodide of potassium and starch.

8. The liquid may stand in contact with finely divided phosphorus for days, without losing the property of turning the iodide of potassium and starch blue on the addition of sulphate of iron solution; but by remaining together longer the power is lost.

When we compare the behaviour of this liquid with that of the artificially prepared mixture of phosphorous acid and peroxide of hydrogen, we see between the two the most perfect accordance, and the resemblance warrants us in drawing the conclusion that the liquid contains HO_2; and that by the slow combustion of phosphorus in atmospheric air, or attenuated oxygen peroxide of hydrogen (as well as phosphoric and phosphorous acids) is formed; and, indeed, under favourable circumstances in considerable quantity.

It is easy to obtain a fluid which mixed with a solution of permanganate of potash gives, proportionately, at least, a large quantity of oxygen. If we place six pieces.

[1] *Journal für Praktische Chemie*, Bd. lxxviii. S. 63. *Chemisch Central Blatt*. Jan. 18, 1860.

an inch long, of tolerably thick phosphorus in a correspondingly large open porcelain dish, and cover half the circumference of phosphorus with water, and leave it exposed to the action of atmospheric air for about twenty hours at a temperature of 64° F., we shall obtain a liquid 10 cubic centimetres of which mixed in a graduated tube with a solution of permanganate of potash will develope 12 cubic centimetres of ordinary oxygen, indicating the presence of a considerable quantity of peroxide of hydrogen. Under favourable circumstances the author has obtained liquids which were still more strongly charged with HO_2.

It may certainly appear remarkable, that peroxide of hydrogen can exist in the presence of phosphorous acid which is considered easily oxidisable, and which is so ready to part with some of its oxygen to a number of oxidisable substances: it seems strange that even phosphorus can remain in contact with HO_2 without immediately reducing the same to water. But we are already acquainted with many instances of a like kind, as, for example, ozonised oil of turpentine and the similarly circumstanced ether, in which mixtures as well, active oxygen exists in contact with otherwise easily oxidisable matters.

So long as no ozonized oxygen (−O) appears, not the least trace of peroxide of hydrogen (HO+[+O]) can be discovered in the water which touches the phosphorus exposed to the action of atmospheric air, ; but as soon as ozonisation has taken place HO_2 is discoverable in the water. The simultaneous appearance of (−O) and HO+(+O) may be easily demonstrated in the following way. We place a few grammes of phosphorus with a clean surface, divided into several pieces, in a beaker with only sufficient water to partly cover the phosphorus. If the temperature reaches 64° or 68° F. ozonised oxygen soon appears as will be shown by placing a piece of paper moistened with iodide of potassium and starch in the neighbourhood of the phosphorus. If we now give the glass a rotatory motion so that the liquid may cover the phosphorus and then run off again, and continue the motion for only a few minutes, the water when poured off will be found to contain so much peroxide of hydrogen that its presence may be demonstrated by means of the iodide of potassium and starch and a few drops of the iron solution.

Such a simultaneous appearance of ozonised oxygen in the air above the phosphorus, and HO_2 in the water which touches the phosphorus seems the more extraordinary as the author's latest experiments show that −O and HO+(+O) are by shaking together converted into ordinary oxygen.

However long ozonised or ordinary oxygen was treated with water, no trace of peroxide of hydrogen was produced, which negative proof may justify the conclusion that the HO_2 formed by the slow combustion of phosphorus is produced neither from the ozonised nor the ordinary oxygen—a fact already made probable by the single circumstance that the active oxygen in the peroxide of hydrogen is in the (+O) condition, while that in the ozonised oxygen =(−O) and ordinary oxygen =O.

As HO+(+O) is not formed from HO and (−O) nor from O, and as it is a fact that HO_2 is only produced when ozonised oxygen appears, the question arises — in what causal connection does this simultaneous appearance of positive and negative active oxygen stand.

With regard to (−O) and (+O) which appear with the slow combustion of phosphorus, (−O) in a free state and (+O) in combination with water: it is certain that both are formed from ordinary O, which fact must lead to the conclusion that by contact with phosphorus the inert or neutral oxygen is split up, polarised or decomposed (*differencirt*), into two oppositely active conditions, or however otherwise we may describe this remarkable phenomenon.

As water is combinable with positive-active oxygen, it accordingly absorbs it to form peroxide of hydrogen, whilst part of the negative-active oxygen appearing at the same time escapes, on account of its gaseous nature, into the atmosphere above the phosphorus, the greater part combining to form phosphorous acid, which for the above reason, like phosphorus itself, can remain in contact with peroxide of hydrogen without abstracting its active oxygen. It is possible and even probable that part of the (+O) and (−O) produced by the polarising influence of phosphorus are immediately reconverted into O or ordinary oxygen.

From the preceding communication it seems that the changes produced by the slow combustion of phosphorus are less simple, but more interesting than was formerly thought, and the author is convinced that in this instance a chemical fundamental phenomenon lies before us, which when it shall have become rightly and perfectly understood, cannot fail to lead to the enrichment of theoretical chemistry.

Naturally we are not yet in a position to answer the first questions which arise; on what ground the (+O) and (−O) conditions of oxygen rest, and how phosphorus polarises chemically the neutral oxygen. The single thing in the interest of science that we can do at present is to demonstrate that this chemical polarisation effected by phosphorus is not an isolated instance but a common fact.

On the Carbonates of Alumina, Sesquioxide of Chromium, and Iron, by James Barratt, *Student in the Liverpool College of Chemistry.*

Having seen a notice of a recent paper by Dr. Wallace in the *Chemical Gazette* for 1858, vol. xvi. p. 411, I was induced by Dr. Muspratt to repeat some experiments made under his inspection some years ago, upon the carbonate of alumina, as also those of Dr. Wallace on this and the other carbonates above referred to.

Carbonate of Alumina. — Dr. Wallace prepared the alumina salt by precipitating a solution of chloride of aluminium by one of carbonate of soda, both being highly dilute. This precipitate, after being well washed on a filter, was levigated with water, then re-filtered, and subjected to prolonged washing; finally it was dried over sulphuric acid till no further loss of weight was experienced. On analysis, the desiccated mass yielded the formula:

$$3Al_2O_3.2CO_2 + 9HO. \text{ or, } 2(Al_2O_3.CO_2 + 3HO) + Al_2O_3.3HO.$$

The experiment of Mr. Joseph Danson above referred to, afforded the annexed composition, $3Al_2O_3.2CO_2 + 16HO$; Langlois obtained $8Al_2O_3.3CO_2 + 40HO$. Whilst, according to Saussure, the compound contains *no carbonic acid whatever*. The above statements are certainly most conflicting. I prepared the alumina campound precisely in the same manner as prescribed by Dr. Wallace. After washing it for two days, it was dried and analysed: the carbonic acid amounted to *three per cent.* It was then triturated in a mortar with water, thrown upon a filter, edulcorated repeatedly with water, and redried as before over sulphuric acid. On analysis the annexed results were obtained, corresponding with the simple hydrate of alumina.

	Atomic Weight.	Theory.	Found.
1 equivalent of alumina .	51	65·384	65·030
3 „ water .	27	34·616	34·970
Carbonic acid . .	-	-	none
	78	100·000	100·000

From the above it is evident that when an alumina salt is precipitated by an alkaline carbonate, there is no carbonate of alumina formed. The three per cent. of carbonic acid found in the first instance was in all probability due to the retention of some of the precipitant (carbonate of soda) by the hydrated alumina.

Carbonate of Chromic Oxide.—This compound was prepared by acting upon chloride of chromium in the same way as stated in regard to the preceding salt. It was a greenish powder, which yielded the formula undermentioned:

To Dr. Wallace . . . $Cr_2O_3.CO_2 + 4HO$
„ Berzelius . . . $4Cr_2O_3.CO_2 + 3HO$
„ Langlois . . . $2Cr_2O_3.CO_2 + 6HO$
„ Meisner . . . $10Cr_2O_3.7CO_2 + 8HO$
„ Lefort . . . . $Cr_2O_3.CO_2 + 4HO$.

Here again we see various statements, evidently owing to the different stages of washing at which the compound had been subjected when taken for analysis. Subjoined are the results I obtained with the above salt.

	Atomic Weight.	Theory.	Found.		
			1.	2.	3.
1 equivalent of sesquioxide of chromium . .	77	57·030	57·594	56·956	57·231
1 equiv. of carbonic acid . .	22	16·300	16·000	15·231	15·357
4 equiv. of water	36	26·670	26·046	27·813	27·422
	135	100·000	100·000	100·000	100·000

Formula $Cr_2O_3.CO_2 + 4HO$.

Carbonate of Ferric Oxide.—This compound was prepared by precipitating a dilute solution of sesquichloride of iron with one of carbonate of soda, and after thorough washing, dried in the air at 70° to 75°. It yielded to Dr. Wallace the formula:

$3Fe_2O_3.CO_2 + 16HO$ or $Fe_2O_3.CO_2 + 2(Fe_2O_3.3HO)$

When the desiccation was effected at 212° it afforded:

$3Fe_2O_3.CO_2 + 4HO$ or $Fe_2O_3.CO_2 + 2(Fe_2O_3.2HO)$

Dr. Wallace remarks, "when washed *until a very minute trace of soda existed in it*"—(the italics are mine). After being kept many weeks in water, dried, levigated, and rewashed, analysis gave the following composition:

$9Fe_2O_3.CO_2 + 12HO$ or $Fe_2O_3.CO_2 + 4(2Fe_2O_3 + 3HO)$

Soubeiran found a specimen exposed in a damp cellar for six months to yield $5Fe_2O_3.CO_2 + 12HO$. Langlois dried the salt at 212°, and found it contained only 1·36 per cent. of carbonic acid. I found the composition of the iron compound dried in the air to be:

	Atomic weight.	Theory.	Found.
3 equivalents of sesquioxide of iron . .	240	71·856	72·000
1 equivalent of carbonic acid	22	6·586	7·037
8 equivalents of water .	72	21·558	20·963
	334	100·000	100·000

Formula $3Fe_2O_3.CO_2 + 8HO$

Dried at 212° it gave me:

	Atomic weight.	Theory.	Found.
3 equivalents of sesquioxide of iron . .	240	80·540	80·770
1 equivalent of carbonic acid	22	7·370	7·250
4 equivalents of water .	36	12·090	11·980
	298	100·000	100·000

The preceding examinations were all most carefully performed under the direction of Dr. Muspratt, who with myself *cannot account* for the *whole* of the carbonic acid being removed from the alumina and *not from* the other two oxides; such however is the fact, as proved by the foregoing experiments, all of which were conducted on the same plan, and each precipitate was apparently submitted to the same conditions and treatment.

TECHNICAL CHEMISTRY.

On a Continual Indicator of the Specific Gravity of Gas, by Drs. J. Bosscha *and* L. C. Ledoir, *Leyden University.*

Several gas-engineers may have felt the want of an instrument of simple construction, serving to determine by an easy experiment, the more or less valuable qualities of gas issuing from different kinds of coal, and from coals of the same kind subjected to different degrees of heat.

Considering that the lighting power of gas, according to the experiments of Clegg and others, corresponds directly to its specific gravity, we tried a series of experiments with apparatus based on the principle just explained, but of different constructions, and at last succeeded in devising an instrument answering all the conditions required.

This apparatus simple in its application, may perhaps be found useful in gasworks. Its construction may be easily conceived by the following indications: A glass balloon having a volume of about half a litre (=30 cubic inches=1 wine pint) is hung at one end of a balance with an inflected beam, such as used for ascertaining the weight of letters. The accuracy and sensibility of this balance must be so great that variations in weight of one milligramme (=0·01 English grain) make themselves visible on the circular scale, over which the longest downwards inflected end of the beam moves.

The whole apparatus is placed under a glass vessel, having an in- and outlet for the coal-gas, and standing in a pneumatic trough.

It will easily be understood that if the vessel is filled with gases of different specific gravities at the same degree of heat and pressure, the beam of the balance will assume a different position, and each position will correspond to a different specific gravity of gas. Our scale is divided into equal degrees and their value fixed by filling the vessel first with pure hydrogen and afterwards with air. The weight of the glass balloon must be as low as possible; the one we made use of had, together with the hook, a weight of no more than 45 grains.

It seems not difficult for micro-chemical glass apparatus makers to blow balloons of the proportions just described, but they have the disadvantage of being very fragile.

PHARMACY, TOXICOLOGY, &c.

On the Preparation of the Unguentum Hydrargyri Nitratis, (Ph. L.) by Julius Schweitzer.

No preparation of the London Pharmacopœia is more difficult to obtain of a constant and uniform appearance and consistence than the unguentum hydrargyri nitratis. The ingredients which enter into the composition of this ointment are lard, olive oil, mercury, and nitric acid; and it is directed to be prepared by first dissolving the mercury in the nitric acid, and then mixing the solution while hot with the lard and olive oil previously melted together. When successfully made the ointment should be, 1. of a pure pale yellow colour; 2. of a soft and uniform consistence; and 3. should be able to retain its colour and softness unchanged. When the acid mercurial solution is mixed with the melted lard and oil, we observe a chemical action accompanied by a rise of temperature to take place, which is more or less observable according—1. to the state of the mercurial solution; 2. to the temperature of the lard and oil at the time the solution is added; and 3. to the amount of stirring employed to effect the combination. The chemical action arises from the influence of the nitrous acid in the mercurial solution on the lard and oil. The warmer the fats, the richer the nitric solution in lower oxides of nitrogen, and the more energetic the stirring, the more sudden will the chemical action take place, and the higher will rise the temperature of the mixture; and on the contrary, the cooler the fats, the poorer the mercurial solution in nitrous acid, and without stirring, the mixture occasions scarcely any chemical action and rise of temperature at all. As a sudden and high temperature is always detrimental to the ointment, we must especially guard against this, which is perfectly in our power. But as we have to assist, and to some extent develope, chemical action to produce the ointment, we must remember, 1. that the *larger* the amount of nitrous acid in the solution the *lower* must be the temperature of the fats when the mixture is made, and 2. that the *poorer* in nitrous acid the *higher* may the temperature of the fats be. It must always be borne in mind, however, that ointments whose temperature in the making rises above 212° Fahr. will turn out dark in colour and hard in consistence, even if the colour and consistence is tolerably good when first made; but those which are made at a lower temperature will always prove unobjectionable in every respect.

I divide the preparation of this ointment into three periods. I allow the solution of the mercury in the nitric acid to go on slowly during the night. The next morning I melt the lard, and after the acid solution is added I watch the chemical action during the day. The following morning the preparation is finished in the manner hereafter described.

As the nitrous acid is the most essential agent in the formation of the ointment, I effect the solution of the mercury so as to lose as little of this acid as possible. I therefore allow the solution of the mercury to go on spontaneously in the cold and in a tall covered jar. I avoid hereby trouble and inconvenience; and in the morning I find a complete solution, cold and ready for use. In the morning I melt the lard on a water bath, strain it into an open glazed pan, and add the oil to it cold to lower the temperature. I stir the two well together, and wait until the mixture is about 130° Fahr., when I pour the mercurial solution gently into it, and allow the whole to stand undisturbed for some time. When the ointment begins to set at the sides of the vessel, and on the surface, I move these solid portions gently, and guide them into the warmer part, and wait again until it is necessary to repeat this operation, now and then drawing the spatula backwards and forwards through the entire mass. As the whole becomes firmer and firmer, I increase the stirring, and continue it at intervals through the whole day. The next morning I find a spongy mass with a high raised crust, rather harder than the interior portion, and generally a small quantity of acid liquid at the bottom of the pan. I now stir and beat the mass vigorously for some time until the spongy ointment softens under the spatula, and the liquid becomes thoroughly mixed, when the colour becomes of a beautiful canary yellow, and my care and trouble are rewarded with an ointment everything that can be desired in appearance and consistence. I have still to add a few words on the ingredients and materials which concern this ointment. First of all I select the finest and best lard, as the goodness of the ointment, its colour and keeping properties, depend a good deal on the quality of this article. Next, I avoid the use of all materials which are likely to be acted on by the acid solution. Even the wooden spatula of the laboratory I suspiciously discard for one of stone ware; and when I have my lard and oil, mercury and nitric acid in proper condition, my last look is to see that my vessels are really perfectly clean.

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN[1].

Friday, 20 Jan. 1860.

On the Influence of Magnetic Force on the Electric Discharge. by John Tyndall, *Esq. F.R.S. Professor of Natural Philosophy in the Royal Institution.*

The intention of the speaker was to bring before the meeting a series of experiments illustrative of the constitution of the electric discharge and of the action of magnetism upon it. The substance of the discourse was derived from the researches of various philosophers, its form being regulated to suit the requirements of the audience.

1. The influence of the transport of particles was first shown by an experiment suggested, it was believed, by Sir John Herschel, and performed by Professor Daniell. The carbon terminals of a battery of 40 cells of Grove were brought within one-eighth of an inch of each other, and the spark from a Leyden jar was sent across this space. This spark bridged with carbon particles the gap which had previously existed in the circuit, and the brilliant electric light due to the passage of the battery current was immediately displayed.

2. The magnified image of the coal points of an electric lamp was projected upon a white screen, and the distance to which they could be drawn apart without interrupting the current was noted. A button of pure silver was then introduced in place of the positive carbon, a luminous discharge four or five times the length of the former being thus obtained. The silver was first observed to glow, and afterwards to pass into a state of violent ebullition. A narrow dark space was observed to surround one of the poles, corresponding probably with the dark space observed in the discharge of Ruhmkorff's coil through rarefied media.[2]

3. The action of a magnet upon the splendid stream of green light obtained in the foregoing experiment was exhi-

[1] The publication of Professor Faraday's sixth and last lecture, on the *Correlation of the Physical Forces*, is unavoidably delayed until next week.

[2] Mr. Faraday noticed this dark stripe while the speaker was making his preparatory experiments.

bited. A small horseshoe magnet of Logemann was caused to approach the light, which was bent hither and thither, according as the poles of the magnet changed their position: the discharge in some cases formed a magnificent green bow, which on the further approach of the magnet was torn asunder, and the passage of the current thereby interrupted. It was Davy who first showed the action of a magnet upon the voltaic arc. The transport of matter by the current was further illustrated by a series of deposits on glass obtained by Mr. Gassiot from the continued discharge of an induction coil.

4. A discharge from Ruhmkorff's coil was sent through an attenuated medium; and the glow which surrounded the negative electrode was referred to. One of the most remarkable effects hitherto observed was that of a magnet upon this negative light. Plücker had shown that it arranges itself under the influence of the magnet exactly in the direction of the magnetic curves. Iron filings strewn in space, and withdrawn from the action of gravity, would arrange themselves around a magnet, exactly in the manner of the negative light.

An electric lamp was placed upon its back; a horseshoe magnet was placed horizontally over its lens, and on the magnet a plate of glass: a mirror inclined at an angle of 45° received the beam from the lamp, and projected it upon the screen. Iron filings were scattered on the glass, and the magnetic curves thus illuminated were magnified, and brought to clear definition upon the screen. The negative light above referred to arranges itself, according to Plücker, in a similar manner.

5. The rotation of an electric current round the pole of a magnet, discovered by Mr. Faraday in the Royal Institution, nearly forty years ago, was next shown; and the rotation of a luminous current from an induction coil in an exhausted receiver by the same magnet was also exhibited, and both shown to obey the same laws.

6. Into a circuit of 20 cells a large coil of copper wire was introduced, and when the current was interrupted, a bright spark, due to the passage of the extra current, was obtained. The brightness and loudness of the spark were augmented when a core of soft iron was placed within the coil. The disruption of the current took place between the poles of an electro-magnet; and when the latter was excited, an extraordinary augmentation of the loudness of the spark was noticed. This effect was first obtained by Page, and was for a time thought to denote a new property of the electric current.

But Rijke had shown in a paper, the interest of which is by no means lessened by the modesty with which it is written, that the effect observed by Page is due to the sudden extinction of the primary spark by the magnet; which suddenness concentrates the entire force of the extra current into a moment of time. Speaking figuratively, it was the concentration of what, under ordinary circumstances, is a mere push, into a sudden kick of projectile energy.

7. The contact-breaker of an induction coil was removed, and a current from five cells was sent through the primary wire. The terminals of the secondary wire being brought very close to each other, when the primary was broken by the hand, a minute spark passed between the terminals of the secondary. When the disruption of the primary was effected between the poles of an excited electro-magnet, the small spark was greatly augmented in brilliancy. The terminals were next drawn nearly an inch apart. When the primary was broken between the excited magnetic poles, the spark from the secondary jumped across this interval, whereas it was incompetent to cross one fourth of the space when the magnet was not excited. This result was also obtained by Rijke; who rightly showed, that in this case also the augmented energy of the secondary current was due to the augmented speed of extinction of the primary spark between the excited poles. This experiment illustrated in a most forcible manner the important influence which the mode of breaking contact may have upon the efficacy of an induction coil.

The splendid effects obtained from the discharge of Ruhmkorff's coil through exhausted tubes were next referred to. The presence of the coil had complicated the theoretic views of philosophers, with regard to the origin of those effects; the intermittent action of the contact-breaker, the primary and secondary currents, and their mutual reactions, producing tertiary and other currents of a higher order, had been more or less invoked by theorists, to account for the effects observed. Mr. Gassiot was the first to urge, with a water battery of 3500 cells, a voltaic spark across a space of air, *before* bringing the electrodes into contact; with the self-same battery he had obtained discharges through exhausted tubes, which exhibited all the phenomena hitherto observed with the induction coil. He thus swept away a host of unnecessary complications which had entered into the speculations of theorists upon this subject.

8. On the present occasion, through the kindness of Mr. Gassiot, the speaker was enabled to illustrate the subject by means of a battery of 400 of Grove's cells. The tension at the ends of the battery was first shown by an ordinary gold-leaf electroscope; one end of the battery being insulated, a wire from the other end was connected with the electroscope; the leaves diverged; on now connecting the other end of the battery with the earth, the tension of the end connected with the electrometer rose, according to a well-known law, and the divergence was greatly augmented.

9. A large receiver (selected from Mr. Gassiot's fine collection), in which a vacuum had been obtained by filling it with carbonic acid gas, exhausting it, and permitting the residue to be absorbed by caustic potash, was placed equatorially between the poles of the large electro-magnet. The jar was about six inches wide, and the distance between its electrodes was ten inches. The negative electrodes consisted of a copper dish, four inches in diameter, the positive one was a brass wire.

On the 16th of this month an accident occurred to this jar. Mr. Faraday, Mr. Gassiot, and the speaker had been observing the discharge of the nitric acid battery through it. Stratified discharges passed when the ends of the battery were connected with the electrodes of the receiver; and on one occasion the discharge exhibited an extraordinary effulgence; the positive wire emitted light of dazzling brightness, and finally gave evidence of fusion. On interrupting the circuit, the positive wire was found to be shortened about half an inch, its metal having been scattered by the discharge over the interior surface of the tube.

10. The receiver in this condition was placed before the audience in the position mentioned above. When the ends of the 400-cell battery were connected with the wires of the receiver, *no discharge passed*; but on touching momentarily with the finger any portion of the wire between the positive electrode of the receiver and the positive pole of the battery, a brilliant discharge instantly passed, and continued as long as the connexion with the battery was maintained. This experiment was several times repeated: the connexion with the ends of the battery was not sufficient to produce the discharge, but in all cases the touching of the positive wire caused the discharge to flash through the receiver.

Previous to the fusion of the wire above referred to, this discharge usually exhibited fine stratification: its general character now was that of a steady glow, through which, however, intermittent luminous gushes took place, each of which presented the stratified appearance.

11. On exciting the magnet between whose poles the receiver was placed, the steady glow curved up or down according to the polarity of the magnet, and resolved itself into a series of effulgent transverse bars of light. These appeared to travel from the positive wire along the surface of the jar. The deflected luminous current was finally extinguished by the action of the magnet.

12. When the circuit of the magnet was made and immediately interrupted, the appearance of the discharge was extremely singular. At first the strata rushed from the positive electrode along the upper surface of the jar, then stopped,

and appeared to return upon their former track, and pass successively with a deliberate motion into the positive electrode. They were perfectly detached from each other; and their successive engulphments at the positive electrode were so slow as to be capable of being counted aloud with the greatest ease. This deliberate retreat of the strata towards the positive pole was due, no doubt, to the gradual subsidence of the power of the magnet. Artificial means might probably be devised to render the recession of the discharge still slower. The rise of power in the magnet was also beautifully indicated by the deportment of the current.

After the current had been once quenched, as long as the magnet remained excited no discharge passed: but on breaking the magnet circuit the luminous glow reappeared. Not only then is there an action of the magnet upon the particles transported by an electric current, but the above experiment indicates that there is an action of the magnet upon the electrodes themselves, which actually prevents the escape of their particles. The influence of the magnet upon the electrode would thus appear to be *prior* to the passage of the current.

13. The discharge of the battery was finally sent through a tube whose platinum wires were terminated by two small balls of carbon: a glow was first produced; but on heating a portion of the tube containing a stick of caustic potash, the positive ball sent out a luminous protrusion, which subsequently detached itself from the ball; the tube becoming instantly afterwards filled with the most brilliant strata. There can be no doubt that the superior effulgence of the bands obtained with this tube is due to the character of its electrodes; *the bands are the transported matter of these electrodes*. May not this be the case with other electrodes? There appears to be no uniform flow in nature; we cannot get either air or water through an orifice in a uniform stream; the friction against the orifice is overcome by starts, and the jet issues in pulsations. Let a lighted candle be quickly passed through the air; the flame will break itself into a beaded line in virtue of a similar intermittent action, and it may be made to sing, so regular are the pulses produced by its passage. Analogy might lead us to suppose that the electricity overcomes the resistance at the surface of its electrode in a similar manner, escaping from it in tremors; the matter which it carries along with it being broken up into strata, as a liquid vein is broken into drops.

SOCIETY OF ARTS, *Wednesday, 1 Feb.* 1860.

THE paper read at this meeting was one by DR. MACGOWAN *On the Arts and Manufactures of Japan*, and though short was highly interesting, being illustrated by numerous specimens of varied nature and importance. After a few remarks upon the remarkable geological features of the island and the attractions it offers to the scientific man, the doctor says:

"I cannot better introduce the subject than by showing this Japanese work, an encyclopædia, entitled *The Wonderful Productions of the Seas and Hills*, evidencing, by the subjects treated and the merit of the typography, their advance in arts and knowledge, filled with spirited cuts of almost every industrial pursuit, commencing with mining, and concluding with whaling, an operation in which we find seamen and shore-men jointly engaged, the former wielding harpoons, the latter employing huge nets.

Let us, in imitation of our methodical encyclopædist, commence with metallurgy.

Gold is abundant in Japan, bearing the relation to silver as 1 to 5, instead of as 1 to 15, as elsewhere. Indeed, the last mail brings intelligence to the effect that silver had been exchanged for gold, weight for weight. This in itself does not demonstrate the existence of extensive auriferous deposits; the abundance of the metal may possibly be the consequence of gradual accumulation, being pent up, as it were, by the system of seclusion so long persevered in by that sagacious people.

These volumes, six in number, afford another illustration of the advanced state of the arts in Japan. It is a work on Numismatics. The elegance of the coloured pictures of the various coins—gold, silver, and copper—of different periods and various principalities is remarkable.

Gold-dust is found in the south of Jesso, in the province of Sado.

The silver coin, or *Ichibu*, is of a very peculiar figure. This metal is found in Dewa, Sado, and Tasimo. It does not appear to be abundant at present, but it promises to become so, from the dollars that are pouring into Nagasaki and Kanagawa from China, Japan coming in for a large share of the drain of silver to the East that now attracts general attention.

Japan, as is well known, is remarkable for its richness in copper.

The first thing which attracts the traveller on landing is the great abundance of this metal and the plentiful manner in which it is used. The gutters and shutters for the houses are of copper; the pillars and verandahs are protected with the same metal. The monumental gateways in the cities are often of copper, and the idols in the temples are formed of the same material; and even before landing the traveller would notice that the vessels are sheathed in all parts with copper — in many instances more for ornament than for use.

If restrictions were not placed upon the exportation of that metal from Japan the markets of the world would be glutted with it for a time. The Japanese are very expert in blending copper with other metals, as shown by the various specimens of bronzes before you.

In iron the Japanese are most deficient. Much of their iron is obtained, as in some parts of China, by washing the sands of the rivers. In the summer season multitudes of men, women, and children may be seen washing the sand, and they take all this pains to get a few specks of black oxide of iron, which is subsequently melted and forged for the purposes of their manufactures. As might be expected from this state of things with regard to iron, their cutlery is of a very inferior description, with the exception of swords, which are in many instances very costly, both from their superior workmanship, and the large amount of gold used in their ornamentation."

This method of working iron-ores, seems especially strange to English ears, but the narrative carries with it an example of a great and important truth, viz. — that the physical properties of a metal, or indeed of any natural production, form the only true criterion of its value, which is not dependant so much upon the comparative abundance or scarcity of the substance itself. Among other things Dr. Macgowan exhibited a carpenter's saw and file, a small reaping hook, and two costly swords, of native manufacture; attached to the scabbard of one of the latter was "a small knife, used for what is known as the *Slowi-kari*, or *happy despatch*, that is, self-evisceration."

Calling attention to the peculiarities of these weapons, the lecturer observed: —

"It is stated that these swords will sever a nail without being notched. They are made out of good bar steel, and tempered by being covered with a paste consisting of powdered porcelain, charcoal, and potash, dried in the sun, brought to a white heat, and then plunged into tepid water. The shagreen on the handle, the massive gold ornamentation, and above all the singular mode of combining gold and iron in decorating the hilt, are all worthy of notice."

The information relating to other mineral productions was given as follows: —

"There are also mines of antimony, tin, lead, and mercury, and perhaps no country in the world of the same area presents so many volcanoes in operation. Sulphur, of course, is very abundant. But, what is more important for civilisation and Christianity as well as for the commerce of the Pacific, coal is found in considerable abundance.

This precious mineral, so necessary for the commerce and

civilisation of the Pacific, is found in nearly all the islands which girt eastern Asia, from Borneo to Sagallen. The first-named locality has fallen into the hands of the British, the last-named, probably the richest, has become Russian property. The Chinese in Formosa and the Japanese at home, will, it is to be hoped, furnish supplies of coal, should either of the others fail for a season. I have visited several of the mines in Japan, and am inclined to attribute the inferiority of the mineral to unscientific mining.

The Japanese themselves have not been insensible of this, and at once ordered, through the Dutch, suitable machinery, but either the machinery was defective, or the requisite skill was wanting for rendering it available. I saw some of it rusting at Desima, and found the miners labouring at every disadvantage, under circumstances, I may add, calculated to throw doubts on the glowing accounts that have been rendered of the comfortable condition of the labouring class in that country.

On the coast of Fizen, I believe, there is as much suffering amongst the labouring classes of Japan as in any part of the world. I have seen them, on a bitter cold day, the children naked and the women nearly so, crawling on all-fours up a hill side, dragging small coal-cars attached to their loins, and I longed for the time when machinery would be brought to their aid."

Passing to the vegetable kingdom the doctor showed some specimens of hard woods, which he said would be very valuable to our shipmasters, carpenters, &c. if they proved to be abundant. The "vegetable wax, "Japan varnish," and the "paper mulberry," were all noticed in their turn, and some interesting fabrics of silk and cotton exhibited, as well as some specimens of edible seaweed, in which latter article a large trade is carried on with China. In conclusion, Dr. Macgowan adverted to the probable introduction of opium into Japan, and lamented the evils that would inevitably follow the use of the drug in large quantities by the ingenious but rather sensual inhabitants. The meeting terminated with a vote of thanks to the doctor for his paper.

If we were inclined to review the paper critically, we might perhaps point out some important omissions, as little or no mention was made of the more artistic accomplishments of the Japanese. Their style of art is certainly peculiar and original, being easy and natural, without displaying either that wearying uniformity so common in our schools of design on the one hand, or the least tendency towards the doctrines of the pre-Raphaelite system on the other. But a few years back we had an opportunity of inspecting some ceramic work of Japanese origin, of which the material, colouring, and design were alike admirable. Among these specimens were some vases, saucers, &c. with natural objects of a simple kind reproduced with exquisite delineation upon their surfaces. There would appear, for instance, on a dark red or claret ground, a large leaf of delicate hue, *not placed exactly in the middle with a border all round*, but easily and gracefully lying on the saucer, as if it had settled there accidentally; sometimes a lizard or other small animal would also be depicted, but if the object happened to be too large for the diameter of the vessel, it would be carried over the edge and completed on the other side. In a word, both in the ceramic and textile manufactures that we had the pleasure of examining, the leading features were a finished detail and an entire absence of artificiality. We think that British art may some day learn a useful lesson from the "Land of the Rising Sun," and the Committee of Council on Education would do well to place a really good and comprehensive collection of Japanese productions at the South Kensington Museum for the public benefit at the earliest opportunity.

Of the scientific attainments of the Japanese we can gather little or nothing from Dr. Macgowan's paper, but his future lectures may perhaps give us more information upon this subject.

PHARMACEUTICAL SOCIETY, 1 *Feb.* 1860.

T. N. R. Morson, Esq. *President, in the Chair.*

Mr. D. Hanbury Junr. exhibited a large mass of Gum Labdanum, which he had received from Candia. It was formerly in great repute as a remedy for the plague; but since the plague has disappeared the gum is neglected, and is now not often to be met with.

Professor Bentley called the attention of the meeting to a paper *On Camomiles* which had been published in France, in which it was asserted that the Chamomilla Romana (as our Anthemis Nobilis is called on the continent) is extensively adulterated with the flowers of Matricaria Parthenium or Pyrethrum Parthenium. The Professor exhibited some of these flowers, and explained the distinctive characteristics of the Pyrethrum and the Anthemis Nobilis. The flowers greatly resembled each other in general appearance, the involucrum in both was hemispherical and scaly; but the anthemis nobilis was distinguished by a conical receptacle which the pyrethrum did not possess.

Mr. Hanbury said the flowers were so much alike that purchasers might be readily deceived, taking the matricaria parthenium for poor or bad camomiles.

Dr. Redwood then proceeded to give an account of some experiments on *Hydrargyrum cum Cretâ*, which he had undertaken in consequence of the statements made on the trial of Dr. Smethurst, that this medicine commonly contained arsenic and antimony. He also referred to a letter published in the *Medical Times and Gazette*, in which the writer affirmed that *Hydrargyrum cum Cretâ* was often prepared with the refuse amalgam of looking-glass makers, from which it was possible that the foreign metals might be derived; and that he and other medical men had been compelled to give up the use of this medicine in consequence of the severe vomiting and other disagreeable effects which they had constantly observed to follow its administration. Dr. Redwood had obtained from various sources different specimens of the medicine, some of them from the largest manufacturers of the article in London, and some which had been in commerce at a time antecedent to the death of Miss Banks. He had submitted all these specimens to a most rigid examination, and the result was that he had been unable to discover the faintest trace of either arsenic or antimony. The tests were so extremely delicate, and the reagents used in the examination were so often themselves contaminated with arsenic, that it was far more probable the small quantity of this metal one gentleman said he had found was derived from the latter than from the grey powder under examination. Dr. Redwood then, on the supposition that it was a common opinion among medical men that the effects of *Hydrargyrum cum Cretâ* were different at the present time from what they used to be years ago, proceeded to account for and explain the fact. He believed that it was a consequence of the different method of manufacture pursued. Formerly the mercury and the chalk were merely rubbed together in a mortar until the mixture of the two was complete; but now, in the wholesale manufacture by machinery, the ingredients were submitted to much more trituration, and the result, he believed, was the formation of much more oxide of mercury, and to this he thought the symptoms complained of might be ascribed. The assertion that the refuse amalgam of looking-glass makers was used in the preparation he believed to be a mistake; but if it were true that would not account for the presence of arsenic, inasmuch as the tin used in the manufacture must be absolutely pure. A mixture of bismuth, arsenic and antimony, a sort of fusible metal, was used for silvering glass globes, but no mercury was used in that process. Moreover, mercury and arsenic only amalgamated with great difficulty, and then the amalgam did not possess the brilliancy necessary for looking-glasses; in fact, the presence of a very small quantity of arsenic would be indicated by the physical appearance of the amalgam.

The Chairman said it was well known that the refuse amalgam of the looking-glass makers and the scrapings of broken-

looking-glasses were collected, and the mercury distilled off; but there could be no objection to the use of this mercury, inasmuch as it would be pure. The difference in the effects of the medicine he attributed to the method of manufacture. The original process produced an inactive, the new method an active medicine.

Dr. ANDREW CLARK said that the two professions were equally indebted to Dr. Redwood for the examination he had undertaken. The injury done by rash statements of the kind noticed was very great. He had used *Hydrargyrum cum Cretâ* largely himself, and he had very carefully observed the results. In his hospital practice he was in the habit of seeing about 600 patients weekly, and he though the prescribed grey powder for 250 of them, but he had never seen the bad effects which had been ascribed to the medicine.

Mr. CUPISS said he had administered a good deal of grey powder, and he had never seen nausea or vomiting produced by it even in the most delicate children. Those who had seen these effects he thought had been peculiarly unfortunate either in their patients or their drugs.

At the end of the meeting Dr. Redwood said he was still occupied with the investigation, and he would feel obliged if any members would send him specimens of *Hydrargyrum cum Cretâ*, particularly if they had been in stock prior to the trial of Dr. Smethurst.

CHEMICAL SOCIETY, 2 *Feb.* 1860.

[Dr. BENCE JONES *in the Chair.*

Dr. GLADSTONE read a paper on an *Iron-sand from New Zealand*. It was found on the shore at New Plymouth, and formed a bank several miles in length and upwards of 40 feet in depth. It was highly magnetic. Examined with the microscope it exhibited small granules of a lustrous black colour which had a distinctly crystalline form belonging apparently to cubic octahedra. To the crystals were attached very minute particles of quartz. An analysis showed the sand to have the following composition (omitting the smaller decimals):

Magnetic oxide of iron	94·0
Silica	3·5
Alumina	1·5
Lime	·5
Various matters and loss	·5
	100·0

It was therefore magnetic oxide of iron in combination with silicate of alumina and lime. Dr. Gladstone said that the occurrence of magnetic oxide in a crystalline form was not infrequent. The sand he thought was the result of the disintegration of some mineral, most likely epidote or garnet.

Mr. FEWTRELL said that the government of New Zealand had offered a premium of a thousand pounds for a process for smelting the sand exhibited.

From a subsequent conversation we learned that the premium had been claimed by a gentleman who was present at the meeting, and that the government of New Zealand had further granted a large tract of forest land to furnish charcoal for the smelting works. There was plenty of limestone in the immediate neighbourhood, and it was expected that the furnaces would soon be in active operation.

Dr. FRANKLAND then read a paper *On the Air of Mont Blanc*. He first gave some account of various analyses of air of different localities; those by Bunsen of the air at Marburg—by Lewey of air taken at sea, and by Schlaginweit among the Eastern Alps. Bunsen had found from a number of experiments that the oxygen present in 100 parts of air ranged from 20·840 to 20·973. The results obtained by Lewey from air taken at sea at 3 P.M. and 3 A.M. were:

	½ P.M.	3 A.M.
Nitrogen	78·886	79·006
Oxygen	21·060	20·961
Carbonic acid	0·054	0·033
	100·000	100·000

The determinations of carbonic acid in the air of the Eastern Alps by Schlaginweit showed in one experiment 0·32 and in another ·058 per cent; but from the manner in which these determinations were made they were not considered of any value. The doctor then said that having ascended Mont Blanc last autumn with Dr. Tyndall, he had taken the opportunity of collecting some air, which he had submitted to analysis, and the results were as follows:

	Grands Mulets.	Summit.	Chamounix.
Nitrogen	79·119	78·989	79·056
Oxygen	20·770	20·950	20·881
Carbonic acid	·111	0·061	0·063
	100·000	100·000	100·000

A diagram was exhibited, showing determinations of oxygen and nitrogen in the air of different localities, by Regnault, Dr. Frankland, and others, some of which we append:

	Oxygen.	*Nitrogen.*
London (Bartholomew's Hospital)	20·885	79·115
	20·999	79·001
Paris	20·913	79·087
	20·999	79·001
Ganges	20·387	79·613
	20·390	79·610
Polar Sea	20·850	79·150
	20·940	79·060

Mr. PERKINS read a paper on *Iodoacetic and Di-iodoacetic Acids and Salts.*

NOTICES OF BOOKS, PATENTS, &c.

Electrotype Manipulation: Part I. Being the Theory and Plain Instructions in the Art of Working Metals by Precipitating them from their Solutions through the Agency of Galvanic or Voltaic Electricity, by C. V. WALKER, *F.R.S. &c. &c. Twenty-ninth Edition.* London: G. Knight & Co.

THE sale of twenty-eight editions of a book is an evidence of its value sufficient to make it quite independent of the commendations of a reviewer. Almost ever since the invention of the art, Mr. Walker's little work has been the text book of every amateur who has begun to experiment in electro-metallurgy, and we can do no better than recommend all who may begin to start with the same manual.

No two discoveries have ever had so great an influence in developing and promoting a taste for the fine arts as the electrotype and photography; but the practical applications of the electrotype have placed it in importance far in advance of its twin discovery. That we have first class maps of fabulous cheapness, that the Art Union can multiply to any extent the productions of our best engravers, and that our low priced periodicals can furnish engravings which surpass in beauty and accuracy the most expensive works of the kind of twenty years ago, we owe to the electrotype. Sanguine as discoverers proverbially are, Mr. Spencer, we imagine, at first little dreamed of the importance of the discovery he had accidentally made. But in his hands it immediately received its most valuable application, and in his paper published in 1839 may be found the germs of almost all that has since been done. Simultaneously with Mr. Spencer's discovery, Professor Jacobi of St. Petersburgh invented a method of converting any line, however fine, engraved on copper, into a relief by a galvanic process; and to these two gentlemen must be awarded the honour of having made one of the most important discoveries of modern times.

It would be interesting, if our space permitted, to trace the rapid development of an art which now ministers to our daily enjoyment—for in some shape or other, the results of the electrotype are ever before our eyes — but we are obliged to forbear. We cannot however pass without notice one unexpected and important sanatory result. The power which

"takes a cast of the eye of a dragon-fly so perfect that under the microscope it exhibits the innumerable facets of the compound eye," and which could with as much ease cover the dome of St. Paul's with gold, if it could only be placed in an apparatus sufficiently large, has banished the old process of water-gilding, which sometimes produced in he operatives the miserable disease known as mercurial intoxication. The mercurial process is now only used for silvering mirrors, and it may be safely predicted that this will in a short time be superseded.

We return to Mr. Walker's book for a description of a *Platinised Graphite Battery* for electrotype purposes, which forms the most important feature of the present edition. Plates of graphite of the required size obtained from gas retorts, are immersed in a mixture of one part of sulphuric acid, and four parts of water, for at least a couple of days and nights. They are then rinced in water and dried. A hole is then drilled in each plate to receive a rivet. The top of the plate is then varnished on either side of the rivet hole, and on both sides of the plate. About an inch in width on both sides in the middle having the rivet-hole in the centre is to be left unvarnished. Electrotype copper is now to be deposited upon the part that is left unvarnished, the object being to provide a surface to which a connecting slip of copper can be soldered. A slip of copper about an inch in width is then prepared and entirely tinned. The copper that has been deposited on the graphite plate is tinned in like mauner. The object of this is to screen the copper from the action of the acid. The slip of copper is next attached to the graphite plate by means of a copper rivet, which has been previously tinned; and then by means of the soldering iron. A strong and perfect connection is thus obtained. The plates are next platinised. A mixture of one part of sulphuric acid and ten of water is prepared. Into this are dropped a few crystals of chloride of platinum, till the liquid acquires a pale straw colour. A battery of three or four Lince's cells is prepared. The graphite plate is connected with the zinc end of the battery, and a couple of platinum plates are connected with the other end. The graphite is placed between the pair of plates, and in a decomposition cell, and the solution of chloride of platinum is poured in till the graphite plate is sufficiently immersed. In from twenty minutes to half an hour the surface of the graphite will be coated with fine black particles of platinum powder. The battery cells are stone jars. The zinc plates are well amalgamated, and are placed with their foot in mercury, contained in a gutta-percha slipper. Batteries of this kind, adds Mr. Walker, are very inexpensive, and are very economical in use.

A Set of Labels for Reagents, and a Table of Atomic Weights of the Elements, intended to accompany Messrs. Nothcote *and* Church's *"Manual of Analysis."* J. H. and J. Parker, Oxford, and 337 Strand, London.

These labels will be found useful to every student who works with the *Manual* of Messrs. Northcote and Church, and he had better fix them under the old names until he becomes thoroughly conversant with the new nomenclature. In this way he will be saved some time and thought, and by constantly reading the formulæ he will soon have them firmly impressed on his memory.

The table of atomic weights should be fixed on a card and suspended in a convenient place, ready for constant reference.

The Practice of hiring Wet-nurses (especially those from the "Fallen") considered as it affects Public Health and Public Morals. Churchill, London.

Wet-nursing is altogether out of our province, and all we can say of this little book is, that the intentions of the authoress are evidently of the very best. We may, however, in illustration, append a story quoted by Southey from Hoare's *Giraldus*.

"In our days a strange occurrence happened in the same district. A wild sow, which by chance had been suckled by a bitch famous for her nose, became so wonderfully active in the pursuit of wild animals, that in the faculty of scent she was greatly superior to dogs who are assisted by natural instinct as well as by human art: an argument that man (as well as every other wild animal) contracts the nature of the female who nurses him."

From the above rather apocryphal story, the practice of hiring wet-nurses from a certain class might be considered as being highly dangerous to the morality of the rising generation.

Improvements in rendering Fabrics and other Substances non-inflammable. Frederick Versmann and Alphons Oppenheim.

Messrs. Versmann and Oppenheim have only patented the use of sulphate of ammonia. They use a solution containing 10 per cent. of the sulphate and apply it to the goods after they have undergone other finishing processes, dipping the goods therein till they are fully saturated, and then drying them. When applied to nets and gauzes with comparatively thick threads and open spaces between them, the patentees use a stronger solution. A neutral solution of the sulphate must be used. The improvements also relate to the application of sulphate of ammonia with starch or other thickening agents.

Recovering Wool from Fabrics.

A patent has been taken out by R. Bell, for recovering wool from old worn-out clothes composed of cotton and wool, such as de-laines. The patentee takes chloride of manganese, such as is ordinarily obtained as a residuum in the manufacture of bleaching-powder; the rags to be treated are then steeped in a solution of this, which entirely decomposes the vegetable or cotton portions and leaves the woollen fibres uninjured. The liquid is then strained through a sieve to retains the wool, which is afterwards washed, dried, and may be used for shoddy or other purposes in making new goods out of old materials, just as new paper is made out of old rags.

Improvement in the Manufacture of Starch.

A patent has recently been obtained by John Hamilton of Belfast for submitting starch — after it is deposited in the manufacturing process — to the action of a hydraulic press, in suitable boxes, so as to press all the water out of it, instead of evaporating all the moisture in artificially heated rooms, according to the usual practice. A great saving in fuel is thus effected by well known and very simple means.

An Improvement in the Manufacture of Cast Steel. R. Mushet.

This consists in producing a superior quality of cast steel by melting malleable iron together with carbonaceous matter and ores, or oxides of titanium or titaniferous iron ores, or titanic acid, or deoxidised titaniferous iron ores.

CORRESPONDENCE.

Chemical Symbols for Druggists' Labels.

To the Editor of the Chemical News.

Sir, — My proposal will no doubt be sufficiently laughed at. and I grant that chemical symbols would be quite inapplicable in very many cases — for instance, tincture of rhubarb could not be well expressed thereby. But I think that they might be often employed with advantage. If plain language must not be used, if hieroglyphics of some sort are necessary, at least let the label, when possible, show the full composition

of the substance. It seems to me that $MgO.SO_3$ would be equally mysterious as Magnes. Sulph., and much more sensible. And would not a druggist's assistant, who learns from the former that sulphate of magnesia is the oxide of a metal combined with an acid, gain more knowledge than from the Dog-Latin of the latter? —I am, &c.

F. C. S.

Mutual Reaction of Salts in Solution.

To the Editor of the CHEMICAL NEWS.

SIR,—An answer is requested to the following query, viz.: What is the reaction of chloride of ammonium on nitrate of potassium?

$$xNH_4Cl + KNO_6 = ?$$

E. G.

[The question which E. G. proposes merits particular notice, and may be profitably discussed. In all cases where no precipitate is produced on mixing two or more salts, where no crystals are deposited or where no gas is evolved, it would appear that the proportions in which the acid and basic constituents of the original salts combine together and rearrange themselves are constant, and that they are independent of the original arrangement. The following conclusions, drawn by Dr. Gladstone from a very extended series of experiments on this subject, embrace almost all that is yet known about it.

The proportions in which the several acid and basic constituents of the salts employed will finally arrange themselves "are not merely the resultant of the various strengths of affinity of the several substances for one another, but are dependent also on the mass of each of the substances in the mixture.

"An alteration in the mass of any one of the binary compounds present alters the amount of every one of the other binary compounds, and that in a regularly progressive ratio; sudden transitions only occurring when a substance is present which is capable of combining with another in more than one proportion.

"This equilibrium of affinities arranges itself in most cases in an inappreciably short space of time, but in certain instances the basic and acid constituents do not attain their final state of equilibrium for hours or even days.

"The phenomena that present themselves where precipitation, volatilisation, crystallisation and perhaps other actions occur, are of an opposite character, simply because one of the substances is thus removed from the field of action, and the equilibrium that was first established is thus destroyed.

"There is consequently a fundamental error in all attempts to determine the relative strength of affinity by precipitation; in all methods of analysis founded on the colour of a solution in which colourless salts was also present; and in all conclusions as to what compounds exist in a solution drawn from such empirical rules as that 'the strongest base combines with the strongest acid.'"

These conclusions are chiefly based upon experiments in which the changes of colour in many coloured salts were examined under conditions which were varied in the most ingenious manner. Advantage was also taken of the different degrees of fluorescence or epipolism exhibited by certain quinine salts when other substances were introduced into their solutions. Dr. Gladstone's paper on the subject is to be found in the *Philosophical Transactions for* 1855, p. 179; while some more remarks further illustrative of the reciprocal decomposition of salts in solution is contained in the *Quarterly Journal of the Chemical Society for* 1856, p. 144. Dr. Gladstone is, we believe, still pursuing the investigation.

To return to the individual reaction mentioned by E. G. The equation given below may perhaps be taken as expressing the final qualitative arrangement of the several acid and basic constituents present.

$$(NH_4Cl + KNO_6) = (x-y)(NH_4Cl + KNO_6) + y(NH_4NO_6 + KCl).$$

It must however be assumed that the solutions of chloride of ammonium and nitrate of potassium are sufficiently dilute to prevent that precipitation of chloride of potassium which would otherwise occur. Suppose that the water were not more than sufficient to retain in solution the NH_4Cl and KNO_6 originally concerned,—when by the mutual action of these salts KCl is formed, a portion of it would be precipitated, since compared with NH_4Cl it requires at the boiling temperature, for instance, double the weight of water for solution.

The equation (to which we have referred above) does not pretend to express the proportions in which the NH_4NO_6 and KCl stand to the NH_4Cl and KNO_6; it assumes, however, that the two new salts, NH_4NO_6 and KCl, are produced in equivalent proportions.—ED.]

Chemical Notices from Foreign Sources.[1]

I. MINERAL CHEMISTRY.

Acids of Phosphorus and Arsenic.—MM. Hurtzig and Geuther[2] have succeeded in transforming tribasic phosphoric acid into pyrophosphoric acid in the moist way by the following method. Yellow phosphate of silver is dissolved in phosphoric acid, and the solution is evaporated. After a time some white scales are deposited, which are separated. The mother liquor is then concentrated afresh, until it has the appearance of a thick syrup when cold. This is treated with ether, and heated to boiling, when there separates a white crystalline powder, which is washed with alcohol to remove the excess of phosphoric acid. The powder, which is not altered by water, is the pyrophosphate of silver $2\,AgO.PO_5$.

By the action of phosphoric acid on the tribasic phosphate of silver there is no doubt formed $\left.\begin{matrix}2AgO\\HO\end{matrix}\right\}PO_5$, which by losing the water under the combined influence of heat and phosphoric acid in excess, is converted into pyrophosphate. The authors have not succeeded in changing pyrophosphate into metaphosphate under the influence of an excess of phosphoric acid.

Arseniate of Silver. — The brown arseniate of silver dissolves easily in a solution of arsenic acid. When this solution is evaporated and kept for some days at a high temperature, there separates a white crystalline powder, which washed with alcohol and dried has the composition expressed by the formula $AgO.2\,AsO_5$. Water decomposes this salt slowly when cold, quickly when hot, into the brown arseniate and arsenic acids.

Action of Perchloride of Phosphorus on Arsenious and Arsenic Acids. — By the reaction of perchloride of phosphorus on arsenious acid, oxychloride of phosphorus and chloride of arsenic are formed, according to the equation:

$$2\,AsO_3 + 3\,PCl_5 = 3\,PO_2Cl_3 + 2\,AsCl_3.$$

When anhydrous arsenic acid is treated with perchloride of phosphorus, there is also formed chloride of arsenic and oxychloride of phosphorus, and chlorine is set at liberty.

$$2\,AsO_5 + 5\,PCl_5 = 2\,AsCl_3 + 4Cl + 5\,PO_2Cl_3.$$

Different States of Silica. — Rose's object in the present memoir[3] is to call the attention of chemists to the isomeric states of silica. Silicic acid presents itself in two states, essentially distinct, and characterised by differences in density and chemical properties. Crystallised silicic acid has a density of about 2·9, and is attacked with difficulty by potash and even by hydrofluoric acid. Rock crystal, quartz, chalcedony, flint, sandstone, and quartzose sand belong to this modification. Amorphous silica dissolves very easily in solutions of potash and soda, and possesses a density = 2·2. This second modification includes gelatinous

[3] *Poggendorff's Annalen*, No. 9. v. cviii.

silica, pulveralent silica resulting from the decomposition of certain minerals, or from the decomposition of fluoride of silicon by water, opals, silica from the carapaces of infusoria, and melted quartz. Amorphous silica has a strong tendency to combine with water, and retains a part of it at temperatures above 212° Fahr.

A perfectly transparent piece of rock crystal exposed to a temperature estimated at 2000° Cent. will not melt, nor will it undergo any change of weight and density. But if the crystal be cracked or if it be powdered, and then exposed to the same temperature, it is transformed into amorphous silica, and the the calcined powder has a density of only 2·394. When rock crystal or quartz is completely fused beads or melted masses are obtained which have a density = 2·2 and dissolve as easily as amorphous silica in alkaline leys or even in a solution of carbonate of soda. These facts exclude the idea that rock crystal or quartz has been formed by fusion. The experiments of MM. Senarmont and Daubrée show that crystallised silica is only formed in the presence of water.

Concentrated fuming hydrofluoric acid evolves heat and boils in contact with silica which has a density = 2·2, but dissolves slowly and tranquilly a finely powdered silica of a density = 2·6.

II. ORGANIC CHEMISTRY.

Kava. — Kava, as the root of the Piper Methysticum is called by the South Sea islanders, is used by them in the preparation of an intoxicating drink. A specimen of the root has been submitted to a chemical examination by M. Gobley[4] who found it to be composed of

Water	15
Cellulose	26
Starch	49
Methysticine	1
Resin (acrid and aromatic)	2
Extractive matter	3
Chloride of potassium	1
Magnesia, silica, alumina, oxide of iron	3
	100

Methysticine is obtained from an alcoholic extract of the root by treating it with hot alcohol, which cooled slowly yields needle-like crystals of a yellow colour. Purified by repeated crystallisations from boiling alcohol, it is procured in the form of white silky needles, which have neither smell nor taste. It is insoluble in water, and but very slightly soluble in alcohol and ether at the ordinary temperature. Boiling alcohol completely dissolves it, but it almost entirely separates on cooling. Hydrochloric acid dissolves and colours it yellow. Nitric acid colours it first yellowish and then orange. Pure sulphuric acid produces a beautiful violet, and the commercial acid a blood-red colour. The composition of methysticine is:

Carbon	62·03
Hydrogen	6·10
Nitrogen	1·12
Oxygen	30·75
	100·00

The resin which is separated from the Methysticine in the repeated crystallisations of the latter is of a greenish yellow colour, has a strong aromatic odour, and a sharp acrid taste. It is insoluble in water, easily soluble in alcohol and ether. Sulphuric acid colours it an intense red, which lasts for some time.

According to Dr. O'Rocke, kava is one of the most powerful sudorifics known. Like the other peppers also, it is useful in catarrhal affections.

Action of Chloride of Lime on some Compound Ethers. — M. Schlagdenhauffen[5] has shown, that the acetates and tartrates of ethyl and methyl, the formiate and nitrate of ethyl, the oxalates of ethyl and methyl, and the benzoate of ethyl furnish chloroform when distilled with a mixture of lime and chloride of lime.

III. CHEMICAL ANALYSIS.

Separation of Peroxide of Iron and Oxide of Copper by Ammonia. — When peroxide of iron is precipitated by ammonia in the presence of oxide of copper, the first always carries down with it a considerable quantity of the second, which cannot be got rid of by washing. M. Loewe[6] says that the two may be completely separated by redissolving the well washed oxide of iron, and precipitating it a second time with ammonia.

Estimation of Silver, Lead, Mercury, Bismuth, and Cadmium, in the state of Sulphurets. — When these metals are precipitated from acid solutions by sulphuretted hydrogen, there is nearly always a mixture of sulphur, which interferes with the correct estimation. M. Loewe[7] has shown that the inconvenience may be remedied by treating the precipitate with a hot moderately concentrated solution of sulphite of soda, which dissolves the sulphur in changing into hyposulphite. The addition of a small quantity of hyposulphite appears to favour the solution of the sulphur.

SCIENTIFIC NOTES AND QUERIES.

Magnetic Peroxide of Iron.—Sir, — A correspondent in a recent number (p. 95) directs my attention to the following quotation from Brande's *Manual* on peroxide of iron.

"When however it has been long and strongly heated it sometimes becomes magnetic."

The product so obtained can in no way be considered similar to the magnetic peroxide of iron described in the first number of the Chemical News, p. 11; in the latter it is not a small portion that is converted into that state but every particle of it is strongly magnetic.

Should *W. G.* be disposed to take the trouble to examine those portions which are sometimes found in the former, I think he will find them to consist of a mixture of peroxide and protoxide caused by loss of oxygen from the excessively high temperature employed. Were precautions taken to prevent access of oxygen during the act of cooling, a much larger proportion would no doubt be found in that condition.

I have subjected peroxide of iron to a white heat for upwards of an hour, but find that temperature insufficient to produce the change mentioned by Brande. Heat not only appears incapable of rendering the peroxide of iron magnetic without change of composition, but when already in that condition will entirely destroy it after long subjection to a high temperature. — *J. Robbins.*

Utilisation of Spent Bark of Tanneries. — Sir, — There is annually a vast quantity of spent bark, often mixed with valonea, (acorn cups from the Levant), thrown away from the tanneries of this and other countries; and many tanners are obliged, at a great expense, to erect kilns in which to burn it, not having kilns to stow it away. When completely decayed it resembles fine black mould, and is used by some farmers to cover manure heaps, as it absorbs the liquor and some of the ammonia.

Of course, it contains a large proportion of carbon, and probably humic and ulmic acid to a small extent. I should be very glad if any of your readers could inform me whether any experiments have been made to test its value. If any use could be found for this spent bark, &c. it would be a great advantage both to the discoverer and to the tanner.

Another thing wanted is an accurate method of testing the amount of tannin in vegetable substances, there being no practical method of doing so, the tanno-gelatin process having many objections. — *W. G. F.*

Conversion of Sulphate of Chromium into Bichromate of Potassa.—Sir, — In Balmain's process for obtaining oxygen by the reaction of concentrated sulphuric acid on bichromate of potassa, the chromic acid is reduced to the state of sesquioxide of chromium, which remains combined with SO_3 and KO.

How may it be economically reconverted into bichromate of potassa?—*E. G.*

MISCELLANEOUS.

Bitumenised Paper Tubing.—An experiment was recently made under the great clock tower, Westminister, for trying the strength, by hydraulic pressure, of a new description of tubing, composed of bitumenised paper, invented by M. Jaloureau, of Paris. M. Jaloureau is a contractor for paving Paris and other towns in France with bituminous concrete. It happened in the course of his experiments that some paper which had been coated with bitumen was laid aside in a coiled form, and after some time it became very stiff and solid. Pursuing the idea which thus accidentally occurred to him, M. Jaloureau put several layers of bitumenised paper round a cylinder, and submitting them to internal pressure, he found that a tube a quarter of an inch in thickness was capable of resisting a pressure of 250 lbs. to the square inch. The municipal authorities of Paris tried these tubes for the conveyance of gas, and in the recent experiments made here a piece of tube was produced, which, though stated to have been under ground in Paris as a gas pipe for twelve months, had the appearance of being a new pipe. The tubes subjected to the pressure of the hydraulic pump bore a strain of 250 lbs. to the square inch without bursting, which is more than they would be ever called on to bear in ordinary use. One of the tubes, half an inch thick, and with a bore of two inches, was also tested by weight, and it only gave way to a pressure of 428 lbs. the bearings being three feet apart. It was stated that the tubes might be submitted to a temperature of 160 degrees of Fahrenheit without any deterioration of the material. The cost of the tubing is said to be less than half that of the ordinary iron piping. Messrs. Paul Joske and Alexander Young are the patentees of the invention in this country.

Coating Electrotype Plates with Iron.—The following process has been successfully employed in coating electrotype deposits with a coating of pure iron; thereby rendering them little inferior to steel plate engravings as regards durability.

Dissolve 1 lb. of sal ammoniac in 1 gallon of rain water, then add 2 lbs. of neutral acetate of iron, boil the solution in an iron kettle for two hours, replacing the water lost by evaporation; when cold, filter the solution, and keep it in close covered vats (when not in use) to prevent oxidation.

The iron plate used in the decomposition cell must be of the same surface as the plate to be coated with iron; a Smee's battery of at least three cells, charged with 1 part sulphuric acid and 60 parts water being used for the decomposition.

To ensure success the following rules must be observed:—1st, The plate must be thoroughly freed from any greasy matter by immersing in a solution of caustic soda, then rinsed in clean cold rain water, after which dip it in dilute acetic acid, and immediately transfer it to the solution of iron; this will ensure perfect adhesion between the metals. 2nd, The solution must be filtered previous to use, to remove the oxyd of iron formed by exposure to the atmosphere. After the plates have been coated with iron they must be well rinsed in clear warm rain water, then in a weak alkaline solution, well dried with a piece of clean soft cotton, and slightly oiled to prevent oxidation.

The coating of iron is very hard and brittle, resembling the white iron used by manufacturers of malleable iron. Should any of the surface be damaged, the whole coating of iron may be removed by immersion in dilute sulphuric acid, and recoated again by the above process.—*Scientific American.*

Food and its Constituents.—Flesh-formers are indispensable to the very existence of the body, which is now believed to waste so fast that every 40 days we may be said to possess a new body. This is certainly fast living, compared with the slow ideas of the last generation of chemical physiologists, who estimated the time for such waste and renewal at seven years; but such is the modern idea, as we have stated, and perhaps the truth lies somewhere in the rather wide interval between forty days and seven years. But although flesh-forming food is thus indispensable, fuel-yielding food is no less indispensable, as the natural heat of the system is kept up by the latter, and not by the former. Fuel-yielding or heat-giving food must consist essentially of three of the four elements of flesh-yielding food, namely, carbon, hydrogen, and oxygen, the nitrogen not being essential to it as a heat-giver, though often still contained, to some extent, in heat-giving food; and indeed, neither is the oxygen of use as a heat-giver in the composition of the food, although it is essential as the evolver of heat when it combines, from the breathed air, with the elaborated heat-giving food of the blood, in the lungs; or burns that food as fuel, in so combining with its hydrogen and carbon, as to convert these into carbonic acid gas and watery vapour, which are sent up the windpipe by the expiratory act of breathing, and so expelled, like so much smoke from a furnace through a locomotive funnel or a chimney. The proximate elements or ingredients of heat-giving food are mainly starch, gum, sugar, and fat, each of these containing more or less of the three necessary elements. Thus fat, sugar, gum, and starch are of little or no use in building up the structure of the body, or in repairing its waste. The natural heat of the body is 98° Fah. This must be kept up by the heat-giving food—easy work for such food in tropical climes or in summer, but somewhat hard labour in the arctic regions, and in winter of the temperate climates. Among heat-giving food are potatoes, carrots, and other vegetables, rice, sugar, and the fat of animal food, the butter of milk, the oils of vegetables, &c. Five ounces of flesh-formers, being the amount required to restore the daily waste of the body, are contained in the quantities given of each of the following vegetable substances:—

	lbs.	oz.		lbs.	oz.
Wheat flour	2	1	Potatoes	20	12
Barley meal	2	6	Carrots	31	4
Oatmeal	1	13	Parsnips	15	10
Maize	2	9	Turnips	17	12
Rye	2	3	Cabbage	10	6
Rice	4	13	Tea (dry)	1	11
Buckwheat	3	10	Coffee (dry)	2	1
Lentils	1	3	Cocoa (nibs)	3	2
Peas (dry)	1	5	Bread	3	13
Beans (dry)	1	5			

To make Paper waterproof.—Dissolve 8 ounces of alum and 3½ ounces of white soap in 4 pints of water; in another vessel dissolve 2 ounces of gum arabic and 4 ounces of glue in 4 pints of water. Mix the two solutions and make the mixture hot. Immerse the paper in the mixture, and then hang it up to dry or pass it between cylinders.

The alum, soap, glue, and gum form a sort of artificial covering which protects the surface of the paper from the action of water, and to a certain extent from fire. This paper will be very useful for packages which may be exposed to the inclemency of the weather.—*Monitor de la Salud.*

ANSWERS TO CORRESPONDENTS.

R. T.—Consult *Ure's Dictionary.*

Yokels.—We cannot put our hand on the receipt just now, but will look again.

De Mouat.—1. All the processes for the preparation of aniline are long and complicated, and the description will occupy more space than we can give in this column. We hope to have an article on the subject soon. 2. It can only be procured direct from America. There is no publisher in London.

J. F. L. (Bury).—See above for aniline.

A Subscriber (Leeds).—1. Drop a little of the suspected spirit of nitre on filtering paper and allow it to evaporate spontaneously. If prepared with methylated spirit a smell of wood spirit will remain. 2. Artificial oil of almonds can be easily recognised alone. The real oil with strong nitric acid yields crystals of benzoic acid, which would not be obtained from the artificial oil. Perhaps the best way of detecting a mixture of real and artificial oil would be to treat an alcoholic solution with sulphuretted hydrogen and ammonia, and see if aniline could be separated.

G. H. (Wakefield).—1. If we saw the results we could better advise our correspondent. 2. Most likely after some time.

M. S. C.—1. To make butyric ether; butter is saponified with a strong solution of potash, the soap is dissolved in the smallest possible quantity of hot strong alcohol; a mixture of alcohol and oil of vitriol is added to the solution until it acquires a strong acid reaction, and the whole is distilled until the distillate no longer smells of apples. It is then rectified by redistillation with chloride of calcium. 2. Ozone cannot be made cheaply in any quantity.

S. Q. L.—Try annatto.

J. C. B.—An earthenware retort can be procured at the Lambeth potteries.

A Subscriber (Northampton).—We have to thank this and numerous correspondents for various suggestions. Our wish is to please all, but we have no desire to realise the fable of the old man and his ass.

P. McO.—No doubt the last opinion is the result of Deville's latest experiments. His process will soon be in use in England, and we shall have an opportunity of testing the truth of the statement.

Aonides.—Consult Knapp's *Technology*, last edition by Ronalds and Richardson.

Inops—*T. S.*—received too late for insertion this week.

*** All *Editorial Communications* are to be addressed to the Editor; and *Advertisements* and *Business* communications to the Publisher, at the Office; 12 and 13 Red Lion Court, Fleet Street, London E. C.

THE CHEMICAL NEWS.

VOL. I. No. 11. — February 18, 1860.

THE ADULTERATION OF FOOD BILL.

GUY-PATIN, in a letter dated March 2, 1655, writes in terms of strong condemnation of the *opera medico-chymica* of Paracelsus, which it was proposed to reprint, and says of chemistry: "La chimie est la fausse monnaie de notre métier. Je voudrais que, pour le bien public, elle fût aussi bien défendue que les faux quart d'écus pour lesquels on a autrefois pendu tant de faux-monnoyeurs." The celebrated physician, when he wrote in such contemptuous language of chemistry, had not the faintest conception of the important position it was destined to attain among the sciences, any more than he could foresee the inestimable benefits which mankind at large have derived from it. There is, however, one direction in which chemical knowledge has been extensively applied for the injury and seldom for the good of individuals, viz. in the adulteration of articles of food. Thus, by its agency bad wine is made to assume the appearance of good; essences of fruit are manufactured into the composition of which fruit never entered; bad flour is converted into the best bread, and we might mention a host of substances which chemistry is employed to adulterate in some way or other, to the wrong of the consumer and the demoralisation of the vendor. Learned and thoughtful physicians, who have well-considered the question, have arrived at the conclusion that a great proportion of the diseases of the digestive organs arise from this universal adulteration of articles of food, and it has therefore become a matter of grave national importance that the legislature should take some steps to put an end to this abominable perversion of scientific knowledge. With this object Mr. Scholefield, assisted by Mr. Wise and Mr. Villiers, has drawn up a bill imposing a penalty on persons guilty of adulterating articles of food or drink. It proposes that any person who shall knowingly sell an article of food or drink with which any noxious substance has been mixed, or who shall sell as pure and unadulterated any article of food or drink which is not pure, shall on conviction before two justices of the peace be fined and made to pay the costs, and in the event of a second conviction the justices shall have power to cause the offender's name and offence to be published in such a manner as they may think advisable. To prevent adulteration by the purchaser the justices must be satisfied that he gave notice to the seller of his intention to have the article analysed, so as to give him an opportunity of seeing it placed in the hands of the analyst. Vestries and district boards in London and town councils in boroughs are to have the power of appointing persons possessing competent medical, chemical, and microscopical knowledge as analysts, and allow them such office and salaries for analysing food and drink as they may think fit. These analysts are to be bound to analyse any articles of food or drink which purchasers may bring to them for a fee ranging from half-a-crown to half-a-guinea, and to give a certificate stating whether it is adulterated, and, if so, whether the foreign substance is injurious to health; and this certificate, in the absence of any evidence to the contrary, shall be received as evidence by the justices, and the cost of the certificate included with the costs attending a conviction. The justices are to have power to cause any article of food or drink to be analysed by any person they may think proper to appoint, who may be required to give evidence at the hearing of the case, the whole of the costs to be borne by the complainant or defendant, as the justices shall determine. Persons convicted before the justices are to be allowed an appeal to quarter sessions. The penalties to be inflicted under this act to be paid to the vestry, district board, or town council, to be disposed of for parish purposes. The expenses attending the carrying out of this act to be defrayed, in the metropolis, out of the fund applicable to the purposes of the metropolitan management act, and in boroughs out of the borough fund. Under the term articles of food is included all alimentary substances not taken as medicine. The addition of water to spirits to reduce the strength is not to be considered as adulteration.

That this bill as it stands will become law we think neither probable nor desirable, but the necessity of such legislation once admitted by Parliament it will be easy to modify it so as to make it more effectual for carrying out the object proposed. In the very first clause there is a stumbling block to the conviction of offenders. It says that the vendor must be cognisant of the adulteration. Now, suppose he says that he was ignorant of the article being adulterated, how will the justices proceed in that case? This will have to be amended, and the law must assume that the vendor of adulterated articles is guilty of the adulteration. The motive for allowing the vendor this loophole of escape is, doubtless, to save him from becoming the victim of the wholesale dealer, but this is unnecessary; the wholesale dealer will cease to adulterate when he knows that the conviction of his customer will inevitably lead to his own exposure and consequent loss of custom. If this is not sufficient, a clause might be inserted giving the convicted retail dealer the power of suing the wholesale dealer for the costs incurred by him in the matter.

Another weak point in the bill is, it appears to us, the power of appeal which it gives to persons convicted. This can only tend to deter public spirited persons from prosecuting adulterators, and does not appear to be of use to protect honest tradesmen, as the evidence on which the conviction is founded in one court will be the same in the other, and as it will rest on a matter of fact no amount of argument can alter it.

Let us suppose that a Paterfamilias, honestly indignant at finding that his coffee is largely adulterated with chicory and dried coffee grounds, or that his milk is a compound mixture, determines on punishing the fraudulent tradesman, and succeeds in getting him fined; Paterfamilias is satisfied, and retires from the court with

that gratifying conviction that he deserves well of his country, which is the reward of prosecutors of abusive or extortionate cabmen; but is the tradesman satisfied? Not at all! He gives notice of appeal, and Paterfamilias has either to attend at the sessions personally or by his agent, or let the thing take its course, and in the event of the conviction being quashed, risking a considerable amount of obloquy for having maliciously attempted to ruin an innocent individual, to say nothing of the possibility of his being forced to pay the costs.

The bill also seems to leave too much to the option of persons who are not likely to be over anxious to carry out its provisions very strictly. It is not sufficient to say that vestries and boards *may* appoint analysts; the imperative mood should be used, and it should be made compulsory on these officials to appoint them, who should, moreover, be obliged to be reasonably active in purchasing articles of food and drink and testing their purity. No mention of this is made in the bill, and for aught that appears to the contrary, the analyst, even if appointed, may sit at ease in his office and wait for individuals to bring him work to do; since it does not appear probable that parish officials, who are themselves for the most part tradesmen, will insist on his being very energetic in the performance of his duties. The enforcement of the bill, if it becomes law, will rest entirely with these parish officials, who may decline to appoint an analyst at all; and even if they are moved by public opinion to do this much they may refuse to order a prosecution, and we all know how certain it would be to become a dead letter if it were left to the public to enforce its provisions. We conceive, therefore, that to make the bill effective its provisions must be made more stringent; and we think that instead of paying the analyst a salary, it would tend more to the effectual carrying out of the object which the promoters of the bill have in view if he were to receive a certain proportion of the fine.

With regard to the punishment to be inflicted on convicted adulterators, we think it might be made heavier than is proposed by the bill. The infliction of a penalty merely would be inadequate to check the system of adulteration, but when to this exposure is added there is good hope that it may be brought to an end. The only question to be considered is the manner of the exposure. To publish the conviction in a newspaper would be useless in the majority of cases, and we therefore think it would be well to adopt the practice pursued in France. On a second conviction let the name of the dishonest vendor, the nature of his offence, and its punishment be published in the *Gazette*, from which the newspapers would be pretty certain to quote it, and a report of it printed and nailed to his own door-post; the whole to be done at his expense. The last method of exposure is the only one in which we place any confidence, for in poor neighbourhoods, where the inhabitants suffer most, a tradesman might be fined a dozen times without his customers becoming aware of it; but if a printed report of the case stared them in the face when they were about to enter the shop it would be a sufficient warning to them to go elsewhere. The number of days during which he should be compelled to expose the placard might be proportioned to the enormity of his offence.

To sum up the amendments we think necessary to make the bill effective: Let the vendor of adulterated articles be assumed to be the adulterator, giving him, if innocent, the remedy we have suggested. Make it compulsory on vestries, &c. to appoint one or more analysts in their respective parishes. Make it obligatory on analysts to purchase and analyse a minimum number of of samples of food and drink each week. Let the exposure on a second conviction be that we have indicated, and let it be prescribed by the law, and not left to the discretion of the justices.

If the bill, amended in the manner we have suggested becomes law, a tradesman will hesitate before yielding to the temptation to increase his profits by defrauding his customers, especially when a few convictions have taught him that there is no kind of adulteration which it is not in the power of chemists to detect.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Estimation of Phosphoric Acid in Manures, Coprolites, Bone-ash, and similar Commercial Substances, by FRANCIS SUTTON, *Norwich.*

[SECOND PART.]

WHEN a compound containing iron as well as phosphoric acid is submitted to analysis by the uranium process described in the first part of this article, the precipitate of phosphate of uranium invariably carries down a portion of iron with it. In this case the colour of the precipitate is altered to a dirty orange-yellow, and possesses a somewhat granular appearance. The quantity of iron depends in some measure upon the length of time the mixture has been kept at a boiling heat. Arendt and Knop found that the fresh precipitate contained about 0·5 per cent. as the following numbers will show:—

Ur_2O_3	78·80
Fe_2O_3	0·46
PO_5	20·65
	99·91

If the boiling be continued for about twenty minutes, the iron is entirely removed from the precipitate, and the solution is coloured red by acetate of sesquioxide of iron. The better way, however, is, not to depend upon this mode of separation, but to use the modification suggested by Arendt and Knop; that is, to reduce the sesquioxide of iron to protoxide, by means of protochloride of uranium.

It may not be amiss here to give the best method of preparing a solution of protochloride of uranium, which promises to be a most serviceable reducing agent in analysis.

Ammonio-carbonate of uranium is to be dissolved in about twice as much hydrochloric acid (diluted with an equal quantity of water) as is necessary for solution. A concentrated solution of bichloride of platinum added in the proportion of about two drops to each ounce of uranium-salt; fine shreds of copper are then to be added in excess, and the mixture boiled for ten or fifteen minutes, or until the liquid assumes a distinct green colour, and the sesquichloride of uranium is reduced to protochloride.

In order to remove the protochloride of copper from the solution it is now to be boiled until, on adding a few drops to some water, an immediate precipitate is produced. Half an hour's boiling is generally sufficient to attain this end. The solution is then to be diluted pretty freely with water, and set aside to cool. When perfectly cold, the copper will in great measure be separated. Hydrosulphuric acid, however, must be passed through the filtered solution till every trace of copper is precipitated and the liquid smells strongly of the acid.

The filtered liquid is now to be poured into a porcelain capsule, and evaporated at a boiling heat, adding some considerable quantity of chloride of ammonium to prevent the precipitation of protoxide and sulphide of uranium, which would otherwise be the case.

As the hydrosulphuric acid is very difficult to remove, the evaporation must be carried on till the liquid corresponding to each ounce of the original uranium salt is reduced to about three ounces. It is absolutely necessary that every trace be removed—if at the end of the operation a precipitate has occurred—it may be dissolved in a little concentrated hydrochloric acid after the clear green liquid has been poured off, and the two solutions mixed and kept for use.

The solution so prepared contains chloride of ammonium, which is of no consequence for the purpose here contemplated; neither is it any hindrance to the preparation of the pure crystals of protochloride of uranium, as on adding excess of ammonia the uranium is precipitated and can be redissolved.

The value of this solution as a means of reducing sesquioxide to protoxide of iron (and probably other higher oxides to lower) cannot be too highly estimated, for at ordinary temperatures it takes place speedily, but at boiling heat, immediately: moreover the change is visible to the eye, for the reddish colour of the solution gives place to green, and so long as this is the case the iron exists in the form of protoxide.

The delicacy of this reaction may be readily seen, if to a solution of sesquichloride of iron a drop or two of sulphocyanide of potassium be added, which produces a blood-red colour: add now a few drops of the uranium solution, and immediately the colour turns to green, showing that a reduction has taken place: this reaction may be made over and over again by adding first iron and then uranium.

To return, however, to the practical bearing of this circumstance upon the separation of phosphoric acid and iron, the following course must be adopted:—

The compound is to be dissolved in the smallest possible quantity of hydrochloric acid (at most 1½ ounce) and the solution of protochloride of uranium added in sufficient quantity to produce a distinct green colour, or until one drop of sulphocyanide of potassium does not show a change to red. Now add ammonia in sufficient quantity to neutralise the free hydrochloric acid, making sure by throwing into the mixture a small piece of litmus paper. Add a solution of acetate of uranium and free acetic acid, together with a few drops of acetate of protoxide of uranium (obtained by precipitating the protochloride with ammonia and redissolving in warm acetic acid), to insure the presence of sufficient protoxide, and heat to boiling.

The mixture must now possess a distinct greenish colour, not a dirty tinge, which shows the presence of undissolved protoxide of uranium. Put aside until the precipitate has settled; when this has *completely* taken place decant the supernatant liquid through the filter; pour hot water over the precipitate, adding some chloride of ammonium, and boil again; repeat the operation once more and the washing is complete: the precipitate may now be thrown upon the filter, dried, and burned as described in the first part of this paper.

I had intended to give the result of some experiments on the separation of phosphoric acid from alumina by means of uranium, but have not been able to complete them satisfactorily. In a future number probably I may be able to do so.

TECHNICAL CHEMISTRY.

Influence of different kinds of Manure on Herbage.

The grasses form a most important tribe of farm plants. Nutritious in their bulky green state, and highly conducive to the health of the stock which browse upon them in our pasture fields, they are no less valuable when dried into hay. The natural history of the grasses has long since been written; they are belonging to one great family of plants — the graminaceous — and possess certain characteristic properties by which we readily recognise them. The chemical and other properties of the grasses vary very considerably. One contains more albuminous compounds; another more mineral ingredients; one is most nutritive at the period of flowering; another contains most nutritive matters when fully matured. It is, however, singular that we are not in possession of reliable data whereby to pronounce an opinion as to the relative merits of the grasses. Science has thrown some light upon this subject; it is but that dim glimmer which prevents our seeing the entire distance before us. There is a dark place which must be illumined, and an ignorance which must be corrected, ere the farmer and the grazier can truly balance the merits and demerits of particular grasses for particular purposes. Chemical analysis alone will not accomplish all that we require, any more than the empiric conjecture of the more practical man; the two must co-operate, and naturally correct and assist each other.

The grasses, like other plants, are amenable to those various physical agencies which influence vegetable life. Heat, air and light exercise their own distinctive functions in modifying the size, &c. of plants. That there is a most intimate connection too between the soil and the character of the vegetation which it naturally bears is well known. It is also a well-known fact that the manures with which we top-dress grass lands very considerably influence the character of the sward, diminishing the proportion of one species of grass and increasing that of another. The laws by which these modifications were effected remained unknown, however, until Messrs. Lawes and Gilbert undertook to investigate the subject. In experiments instituted to test the effects of different manures in simply increasing the valuable yield of grass, they were so struck with the marked effects of some of the manures in destroying certain plants and families of plants that they sought the assistance of the late Professor Henfrey in classifying the plants composing the sward. The plots selected for botanical examination were:—

1. Not manured.
2. Manured with ammoniacal salts alone.
3. „ mixed mineral manures alone.
4. „ do. and ammoniacal salts.
5. „ do. and double quantity of do.
6. „ farm-yard manure.
7. „ do. and ammoniacal salts.

The herbage was classified chiefly into (*a*) graminaceous plants, (*b*) leguminous plants, and (*c*) miscellaneous herbage, principally weeds.

The graminaceous plants formed, at the time of cutting, 75 per cent. of the produce of the unmanured portion; on the part manured with farm-yard manure, they found 87¾ per cent.; 79¾ per cent. when farm-yard manure and ammoniacal salts were used: 72 per cent. on the portion to which mineral manures were applied; 89 per cent. where 40 lbs. of ammoniacal salts alone were used; 79½ per cent. by the same amount of ammoniacal salts and mineral manure; and 97¾ per cent. where the

double allowance of both ammoniacal salts and mineral manures were applied. The quality of the graminaceous herbage varies no less than the proportion of it which composed the herbage under the different manures.

At one time the graminaceous portion of the herbage consisted of 66 per cent. of flowering or seeding stem, and 34 per cent. of leaf and undeveloped stem, on the unmanured plot; 59 per cent. of flowering and seeding stem by mineral manure alone; 40 per cent of the same by ammoniacal salts only; 75 per cent. by the joint application of animal and mineral manures; 67 per cent. by double application of both manures; and 80 per cent. when farm-yard manure and ammoniacal salts were applied.

It has been found that the manures which increase the amount of whole produce also increase, in a very high degree, the proportion of graminaceous herbage, a conclusion which is of no less interest than importance. The foregoing facts also lead to another instructive conclusion, namely, that nitrogenous manures have a special effect in developing the "proportion of leaves and shoots," while mineral manures tend to the increase of the flowering and seeding of the plants; a conclusion of great practical value to the farmer, as it teaches that guano and sulphate of ammonia produce very different results from those mineral manures which depend for their efficacy on their containing the ash constituents of plants. — *Irish Agricultural Review.*

PHARMACY, TOXICOLOGY, &c.

On the Preparation of Ecbaline, the active principle of Ecbalium Officinarum, by JOHN WILLIAMS.

THE *Ecbalium officinarum* (*Momordica elaterium*), or squirting cucumber, appears to have been employed as a purgative from the time of Dioscorides and Pliny, or possibly much earlier: and the so-called extract is the form in which it has usually been administered.

This *extract* is, as is well known to pharmaceutists, produced by a process totally different from that employed for the production of an ordinary extract.

The cucumber is sliced longitudinally, and subjected afterwards to gentle pressure, the juice thus obtained being allowed to remain at rest for ten or twelve hours, by which time a greenish feculent matter will have deposited. The clear supernatant liquor being rejected, the deposited matter is drained on a linen cloth, and afterwards dried at a very gentle heat, and thus we obtain the thin flaky pieces met with in commerce. As may be supposed, this extract is liable to very great discrepancies in strength and quality; for if the pressure used is great, a large percentage of inert matter will be expelled from the cucumbers, and thus the activity of the medicine will be reduced to an important extent.

The quantity of fine extract of elaterium which can be obtained is stated[1] to be about 3 drs. from 1 bushel of the fruit, weighing in the fresh state 40 lbs. Other authorities give quantities varying from 2 drs. to 4 drs., or even more, doubtless dependent upon the amount of pressure and washing the cucumbers were submitted to, and also the length of time the fluid was allowed to stand before the deposited matter was separated.

The activity of the extract of elaterium depends upon a white crystallisable body to which the name *elaterin* was formerly given, but for which the title *ecbaline* is proposed to be substituted. Pereira points out that the quantity of this principle contained in various samples of the extract of commerce varied from 44 per cent. to 33, 26, 15, and in a foreign article it may be found as low as 5 or 6 per cent. From an experiment of his own upon some extract very carefully prepared at Apothecaries' Hall, he concluded that 30 grs. yielded 7·5 grs. or 25 per cent.; and in a trial I have just made, 3 drs. of extract, purchased as the finest commercial article (taken as being probably equivalent to 1 bushel or 40 lbs. of the wild cucumbers), yielded me exactly 36 grs. of white crystallised ecbaline, equivalent to only 20 per cent.

Of course discrepancies like these are much to be deplored in medical practice, and if the active principle only was used in medicine, much greater certainty of effect would doubtless attend the administration of the remedy. The objection to the use of the ecbaline, however, has hitherto been the high cost of producing the article, thus rendering it almost impossible to employ the remedy in any but experimental trials. With a view of removing this obstacle, Dr. R. B. Garrod, one of the committee at present engaged in drawing up the new British Pharmacopœia, suggested that probably other portions of the fruit as well as the juice would, if properly treated, yield a large quantity of the active principle, and proposed to Messrs. Savory and Sons, and afterwards to our firm, that we should experimentally test the feasibility of his process. Upon consulting together, it was determined that the operations should be conducted in our laboratory, and I have now the pleasure of laying the results of our inquiries before the profession.

Dr. Garrod's proposed process for the production of the ecbaline was as follows:— The cucumbers are to be sliced and dried at a gentle heat, but so that no loss of juice shall occur. The dried fruits to be treated with alcohol, and the alcoholic extract thus obtained acted upon with solution of potash, in which the starch, green colouring matter, &c. is soluble, but in which the ecbaline is not only insoluble, but remains perfectly unaffected by the powerful reagent employed. The residuum therefore, dissolved in alcohol and crystallised, will of course give the ecbaline in a state easily rendered quite pure by a subsequent solution in alcohol, digestion with animal charcoal, and re-crystallisation.

It appeared reasonable that by this process *all* the ecbaline contained in the cucumbers would be extracted, whereas by the ordinary process of making the extract, it may be supposed some, or even a large quantity of active principle, may be left in the plant.

One bushel (weighing 40 lbs. in the fresh state) of wild cucumbers was operated upon. They were carefully sliced longitudinally upon an inclined slab, so that any juice yielded during the operation would flow into a vessel placed for its reception. The cut cucumbers were then placed on a seive for 12 hours (but were not pressed in any way), and then placed in earthen pans, in a warm closet, where in the space of 4 days they became completely dry. In this state they weighed 3lbs.

[1] *Pharmaceutical Journal*, vol. i. New Series, p. 325.

5oz. The liquor which had drained from the cucumbers during the cutting and draining was evaporated to dryness by itself at a gentle heat, and yielded 3oz. extract: this we will call extract No. 1.

The dried cucumbers were now placed in a digesting apparatus, with 2 gallons of alcohol, and the temperature was raised to the boiling point. Afterwards they were allowed to digest for 24 hours. Then the tincture was drained and the operation repeated with another 2 gallons of alcohol. The mixed tinctures when filtered, presented a bright green colour, and being placed in a still the alcohol was drawn over. A small quantity of green extract was the result: this extract we will call No. 2.

The extract No. 1 (the evaporated juice) was treated with successive portions of boiling alcohol, until nothing more could be extracted; the filtered tinctures evaporated to dryness, gave a small quantity of greenish extract. This greenish extract was then treated with about 8 times its bulk of hot liquor potassæ. After digesting for a short time, the greater portion of the matter dissolved, leaving, however, when filtered, washed, and dried, 30 grains of nearly white crystalline matter, which proved to be the ecbaline we were in search of.

Extract No. 1 was treated in a like manner, and yielded 57 grains of matter, insoluble in liquor potassæ, but of a dark greenish-brown colour. Both these deposits were then dissolved in boiling alcohol, a very small quantity of pure animal charcoal added, filtered, and allowed to crystallise.

The matter from extract No. 1 yielded 28½ grs. of ecbaline, white and crystallised. The matter, however, from No 2 extract refused to yield crystals, and gave only a dark coloured fatty mass, which after another trial at crystallisation yielded no better result. It was then attempted to dissolve the fatty matter from any ecbaline which might be present by means of a small quantity of cold ether, but no good effect was produced, the whole mass dissolving freely in that menstruum, whereas ecbaline is but slightly soluble in it.

The result of this experiment appeared so unsatisfactory and so different from what was anticipated, that I determined to repeat the experiment, though in a rather different manner.

One bushel of wild cucumbers was again taken. They were cut up with the same precautions as before, catching all the juice carefully; then well bruised in a large mortar, the mass placed upon sieves and allowed to drain. They were then stirred up with about their own bulk of cold water, allowed to drain, and then subjected to strong pressure through very coarse canvas. By this means a considerable amount of juice was obtained, which upon standing separated into three portions —an insoluble green deposit (the extract of elaterium), and a large quantity of coagulated chlorophyll, floating in a clear aqueous liquid. The whole was thrown upon a calico filter, and the solid matter, after being well drained from the liquid portion, dried between chalk stones. When dry it weighed 2½oz. The aqueous portion was evaporated to the consistence of an extract.

The mass of the cucumbers, after the juice had been thus pressed out, was dried as in the first experiment, digested in boiling alcohol twice, and the mixed tinctures strained and distilled. The amount of extract yielded, was, as might be expected, much smaller in quantity than on the previous occasion.

First, the solid matter which had been strained from the juice (which I look upon as equivalent to the ordinary extract of elaterium, though not in so pure or concentrated a form) was treated with successive portions of boiling alcohol until nothing more would dissolve, and the mixed tinctures evaporated to dryness. This we will call extract No. 1.

Then the extract produced by evaporating the aqueous liquor was treated with alcohol, and yielded a small quantity of brown extract, which we will call No. 2.

The thin alcoholic solution of the cucumber-mass, upon standing, separated into two portions. The more liquid portion was evaporated by itself to dryness: this constitutes No. 3, the solid portion of the alcoholic extract of the mass No. 4.

These several extracts were then treated with hot liq. potassæ, and allowed to digest for some hours, then, somewhat diluted, were filtered, washed and dried.

The dried precipitates were treated with boiling alcohol and filtered, and the alcohol allowed to evaporate gave the following results:

No. 1 extract yielded 25 grains of nearly white crystallised ecbaline;

No. 2, 38 grs. of dark brown non-crystalline mass, which appeared to possess none of the properties of ecbaline;

No. 3 yielded 10 grains of a much lighter and crystalline mass, which probably by further purification will yield a few grains of ecbaline;

No. 4 yielded 14 grains of green waxy matter.

The chlorophyll and residual matter which had refused to dissolve in the boiling alcohol to form extract No. 1 was treated with liq. potassæ, by which means a large portion was dissolved, and that which remained behind was again boiled in alcohol; but the result was only a few grains of brown extractive matter quite free from ecbaline.

The conclusion which must be drawn from these experiments is, I think, that the mass of the cucumber after separation of the juice contains so small a quantity of ecbaline that the loss of alcohol and working expenses would not be covered by the value of the substance produced: that the only portion which yields ecbaline is the insoluble deposit from the juice, which we already know under the name of extract of elaterium, this substance yielding the ecbaline with ease: and that the aqueous portion of the juice is perfectly worthless for the purpose.

Thus we find that the quantity of ecbaline yielded by the large bulk of one bushel of cucumbers is only at most 30 grains, and as the labour and expense attendant upon the operation is considerable, it must be evident that the substance must remain a very expensive one to manufacture; and I am inclined to think it very probable that ecbaline can be made (at any rate in London) at a cheaper rate from ext. elaterium itself than direct from the cucumbers.

I may add in conclusion that through Messrs. Savory and Sons I have been able to operate upon some German extract of elaterium. This extract is in appearance similar to ordinary extract of henbane, or liquorice, and is evidently obtained from the plant itself, and was sold as low as 10s. 6d. per lb. It was imagined that this extract might be a cheap source for the production of the ecbaline. One ounce of it was digested with boiling alcohol and the alcoholic extract prepared, which was then treated with the solution of caustic potash in the same manner as the other extract; but I have been unable to obtain even the slightest trace of crystalline matter from it. It would be interesting to know whether the extract itself has *any* cathartic action.

ROYAL INSTITUTION OF GREAT BRITAIN.

A Course of Six Lectures [1] *(adapted to a Juvenile Auditory), consisting of Illustrations of the Various Forces of Matter, i. e. of such as are called the Physical or Inorganic Forces — including an Account of their Relations to each other; by* M. FARADAY, *D.C.L., F.R.S., Fullerian Professor of Chemistry, R. I., Foreign Associate of the Academy of Sciences, Paris, &c.*

LECTURE VI. (Jan. 7, 1860.) *The Correlation of the Physical Forces.*

We have frequently seen during the course of these lectures, that one of those powers or forces of matter of which I have written the names on that board, has produced results which are due to the action of some other force. Thus, you have seen the force of electricity acting in other ways than in attracting; you have also seen it combine matters together or disunite them by means of its action on the chemical force; and in this case, therefore, you have an instance in which these two powers are related. But we have other and deeper relations than these; we have not merely to see how it is that one power affects another—how the force of heat affects chemical affinity, and so forth, but we must try and comprehend what relation they bear to each other, and how these powers may be changed one into the other; and it will to-day require all my care, and your care too, to make this clear to your minds. I shall be obliged to confine myself to one or two instances, because to take in the whole extent of this mutual relation and conversion of forces would surpass the human intellect.

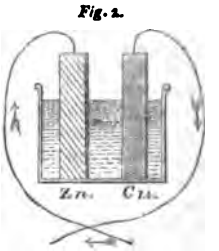
In the first place, then, here is a piece of fine zinc-foil, and if I cut it into narrow strips and apply the power of heat to it, admitting the contact of air at the same time, you will find that it burns; and then, seeing that it burns, you will be prepared to say that there is chemical action taking place. You see all I have to do is to hold the piece of zinc at the side of the flame so as to let it get heated, and yet to allow the air which is flowing in to the flame from all sides to have access to it;—there is the piece of zinc burning just like a piece of wood, only brighter. A part of the zinc is going up into the air in the form of that white smoke, and part is falling down on to the table. This then is the action of chemical affinity exerted between the zinc and the oxygen of the air. I will show you what a curious kind of affinity this is by an experiment which is rather striking when seen for the first time. I have here some iron filings and gunpowder, and will mix them carefully together with as little rough handling as possible; now we will compare the combustibility so to speak of the two. I will pour some spirit of wine into a basin and set it on fire: and having our flame, I will drop this mixture of iron filings and gunpowder through it, so that both sets of particles will have an equal chance of burning. And now tell me which of them it is that burns?—you see a plentiful combustion of the iron filings; but I want you to observe that though they have equal chances of burning, we shall find that by far the greater part of the gunpowder remains untouched: I have only to drain off this spirit of wine and let the powder which has gone through the flame dry, which it will do in a few minutes, and I will then test it with a lighted match. So ready is the iron to burn, that it takes, under certain circumstances, even less time to catch fire than gunpowder. [As soon as the gunpowder was dry Mr. Anderson handed it to the Lecturer, who applied a lighted match to it, when the sudden flash showed how large a proportion of gunpowder had escaped combustion when falling through the flame of alcohol.]

These are all cases of chemical affinity, and I show them to make you understand that we are about to enter upon the consideration of a strange kind of chemical affinity, and then to see how far we are enabled to convert this force of affinity into electricity or magnetism, or any other of the forces which we have discussed. Here is some zinc (I keep to the metal zinc as it is very useful for our purpose), and I can produce hydrogen gas by putting the zinc and sulphuric acid together as they are in that retort; there you see the mixture which gives us hydrogen —the zinc is pulling the water to pieces and setting free hydrogen gas. Now we have learned by experience that if a little mercury is spread over that zinc, it does not *take away* its power of decomposing the water, but *modifies* it most curiously. See how that mixture is now boiling, but when I add a little mercury to it the gas ceases to come off. We have now scarcely a bubble of hydrogen set free, so that the action is suspended for the time. We have not *destroyed* the power of chemical affinity, but modified it in a wonderful and beautiful manner. Here are some pieces of zinc covered with mercury exactly in the same way as the zinc in that retort is covered, and if I put this plate into sulphuric acid I get no gas, but this most extraordinary thing occurs, that if I introduce along with the zinc another metal which is *not* so combustible, then I reproduce all the action. I am now going to put to the amalgamated zinc in this retort some portions of copper wire (copper not being so combustible a metal as the zinc) and observe how I get hydrogen again, as in the first instance—there, the bubbles are coming over through the pneumatic trough, and ascending faster and faster in the jar; the zinc, so to speak, is acting by reason of its contact with the copper.

Every step we now take brings us to a knowledge of new phenomena. That hydrogen which you now see coming off so abundantly does not come from the zinc as it did before, *but from the copper*. Here is a jar containing a solution of copper. If I put a piece of this amalgamated zinc in it, and leave it there, it has hardly any action, and here is a plate of platinum which I will immerse in the same solution, and might leave it there for hours, days, months, or even years, and no action would take place. But now I put them both in together, and let them touch each other. (*fig.* 1.) See what a coating of copper there is immediately thrown down on the platinum. Why is this? The platinum has no power of itself to reduce the metal from that fluid, but it has in some mysterious way received this power by its contact with the metal zinc. Here then you see a strange transfer of chemical force from one metal to another — the chemical force from the zinc is transferred, and made over to the platinum by the mere association of the two metals. I might take instead of the platinum, a piece of copper or silver, and it would have no action of its own on this solution, but the moment the zinc was introduced and touched to the other metal, then the action would take place, and it would become covered with copper. Now, is not this most wonderful and beautiful to see? we still have the identical chemical force of the particles of zinc acting, and yet in some strange manner we have power to make that chemical force, or something it produces, travel from one place to another,—for we do make the chemical force travel from the zinc to the platinum by this very curious experiment of using the two metals in the same fluid in contact with each other.

Fig. 1.

Fig. 2.



Let us now examine these phenomena a little more closely. Here is a drawing (*fig.* 2.) in which I have represented a vessel containing the acid liquid and the slips of zinc and platinum or copper, and I have shown them touching each other *outside* by means of a wire coming from each of them (for it matters not whether they touch in the fluid or outside—by pieces of metal attached they still by that communication between them, have this power transferred from one to the other). Now, if instead of using only one vessel, as I have shown there, I take another, and another, and put in zinc and platinum, zinc and platinum, zinc and platinum, and connect the platinum of one vessel with the zinc of another, the platinum of this vessel with the zinc of that, and so on, we should only be using a series of these vessels instead of one. This we have done in that arrangement which you see behind me. I am using what we call a Grove's voltaic battery, in which one metal is zinc, and the other platinum, and I have as many as forty pairs of these plates all exercising their force at once in sending the whole amount of chemical power there evolved through these wires under the floor and up to these two rods coming through the table. We need do no more than just bring these two ends in contact, when the spark shows us what power is present; and what a strange thing it is to see that this force is brought away from the battery behind me, and carried along through these wires. I have here an apparatus (*fig.* 3.) which Sir Humphry Davy constructed many years ago, in order to see whether this power from the

[1] Reported verbatim by special permission.

voltaic battery caused bodies to attract each other in the same manner as the ordinary electricity did. He made it in order to experiment with his large voltaic battery, which was the most powerful then in existence. You see there are in this glass jar two leaves of gold, which I can cause to move to and fro by this rack work. I will connect each of these gold leaves with separate ends of this battery, and if I have a sufficient number of plates in the battery I shall be able to show you that there will be some attraction between those leaves even before they come in contact: if I bring them sufficiently near when they are in communication with the ends of the battery, they will be drawn gently together, and you will know when this takes place, because the power will cause the gold leaves to burn away, which they could only do when they touched each other. Now I am going to cause these two leaves of gold to approach gradually, and I have no doubt that some of you will see that they approach before they burn, and those who are too far off to see them approach will see by their burning that they have come together. Now they are attracting each other, long before the connection is complete, and there they go! burnt up in that brilliant flash, so strong is the force. You thus see, from the attractive force at the two ends of this battery, that these are really and truly electrical phenomena.

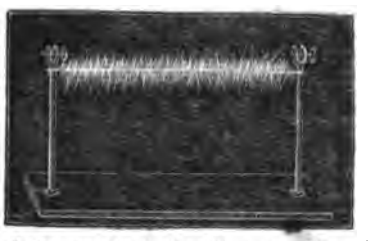
Fig. 3.

Fig. 4.

Now let us consider what is this spark. I take these two ends and bring them together, and there I get this glorious spark like the sunlight in the heavens above us. What is this? It is the same thing which you saw when I discharged the large electrical machine, when you saw one single bright flash; it is the same thing, only *continued*, because here we have a more effective arrangement. Instead of having a machine which we are obliged to turn for a long time together, we have here a *chemical* power which sends forth the spark — and it is wonderful and beautiful to see how this spark is carried about through these wires. I want you to perceive, if possible, that this very spark and the heat it produces (for there is heat), is neither more nor less than the chemical force of the zinc—its *very* force carried along wires and conveyed to this place. I am about to take a portion of the zinc and burn it in oxygen gas for the sake of showing you the kind of light produced by the actual combustion in oxygen gas of some of this metal. [A tassel of zinc-foil was ignited at a spirit-lamp and introduced into a jar of oxygen, when it burnt with a brilliant light.] That shows you what the affinity is when we come to consider it in its energy and power. And the zinc is being burned in the battery behind me at a much more rapid rate than you see in that jar, because the zinc is there dissolving and *burning*, and produces here this great electric light. That very same power which in that jar you saw evolved from the actual combustion of the zinc in oxygen is carried along these wires and made evident here, and you may if you please consider that the zinc is burning in those cells, and that *this* is the light of that burning [bringing the two poles in contact and showing the electric light]; and we might so arrange our apparatus as to show that the amounts of power evolved in either case are identical. Having thus obtained power over the chemical force, how wonderfully we are able to convey it from place to place; when we use gunpowder for explosive purposes, we can send into the mine chemical affinity by means of this electricity; not having provided fire beforehand, we can send it in at the moment we require it. Now here (*fig.* 4.) is a vessel containing two charcoal points, and I bring it forward as an illustration of the wonderful power of conveying this force from place to place. I have merely to connect these by means of wires to the opposite ends of the battery, and bring the points in contact. See! what an exhibition of force we have. We have exhausted the air so that the charcoal cannot burn, and therefore the light you see is really the burning of the zinc in the cells behind me—there is no disappearance of the carbon, although we have that glorious electric light; and the moment I cut off the connection it stops. Here is a better instance to enable some of you to see the certainty with which we can convey this force where under ordinary circumstances chemical affinity would not act. We may absolutely take these two charcoal poles down under water, and get our electric light there;— there they are in the water, and you observe when I bring them into connexion we have the same light as we had in that glass vessel.

Now besides this production of light we have all the other effects and powers of burning zinc. I have a few wires here which are not combustible, and I am going to take one of them, a small platinum wire, and suspend it between these two rods which are connected with the battery, and when contact is made at the battery see what heat we get. (*fig.* 5.) Is not that

Fig. 5.



beautiful?—it is a complete bridge of power. There is metallic connection all the way round in this arrangement, and where I have inserted the platinum, which offers some resistance to the passage of the force, you see what an amount of heat is evolved,—this is the heat which the zinc would give if burnt in oxygen, but as it is being burnt in the voltaic battery it is giving it out at this spot. I will now shorten this wire for the sake of showing you that the shorter the obstructing wire is, the more and more intense is the heat, until at last our platinum is fused and falls down, breaking off the circuit.

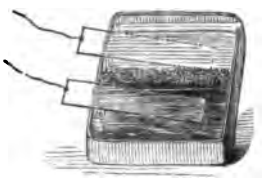
Here is another instance. I will take a piece of the metal silver and place it on charcoal connected with one end of the battery, and lower the other charcoal pole on to it—see how brilliantly it burns. (*fig.* 6.) Here is a piece of iron on the charcoal,

Fig. 6.

see what a combustion is going on; and we might go on in this way burning almost everything we placed between the poles. Now I want to show you that this power is still chemical affinity —that if we call the power which is evolved at this point *heat* or *electricity*, or any other name referring to its source, or the way in which it travels, we still shall find it to be chemical action. Here is a coloured liquid which can show by its change of colour the effects of chemical action; I will pour part of it into this glass and you will find that these wires have a very strong action. I am not going to show you any effects of combustion or heat, but I will take these two platinum plates, and fasten one to the one pole and the other to the other end, and place them in this solution, and in a very short time you will see the blue colour will be entirely destroyed. See, it is colourless now,—I have merely brought the end of these wires into the solution of indigo and the power of electricity has come through these wires and made itself evident by its chemical action. There is also another curious thing to be noticed now we are dealing with the chemistry

of electricity, which is that the chemical power which destroys the colour is only due to the action on one side. I will pour some more of this sulphindigotic acid into a flat dish and will then make a porous dyke of sand separating the two portions of fluid into two parts (*fig.* 7.) and now we shall be able to see whether there is any difference in the two ends of the battery, and which it is that possesses this peculiar action. You see it is the one on my right hand which has the power of destroying the blue, for the portion on that side is thoroughly bleached, while nothing has apparently occurred on the other side. I say *apparently*, for you must not imagine, that because you cannot perceive any action none has taken place.

Fig. 7.

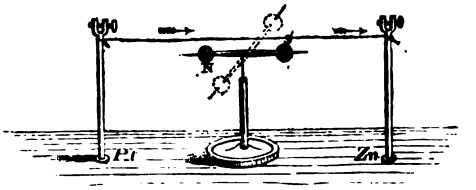


Here we have another instance of chemical action. I take these platinum plates again and immerse them in this solution of copper from which we formerly precipitated some of the metal, when the platinum and zinc were both put in it together. You see that these two platinum plates have no chemical action of any kind, they might remain in the solution as long as I liked, without having any power of themselves to reduce the copper; but the moment I bring the two poles of the battery in contact with them, the chemical action which is there transformed into electricity and carried along the wires, again becomes chemical action at the two platinum poles, and now we shall have the power appearing on the left hand side, and throwing down the copper in the metallic state on the platinum plate; and in this way I might give you many instances of the extraordinary way in which this chemical action or electricity may be carried about. That strange nugget of gold, of which there is a model in the other room, and which has an interest of its own in the natural history of gold, and which came from Ballarat, and was worth 8000*l.* or 9000*l.* when it was melted down last November, was brought together in the bowels of the earth, perhaps ages and ages ago, by some such power as this. And there is also another beautiful result dependent upon chemical affinity in that fine lead-tree, the lead growing and growing by virtue of this power. The lead and the zinc are combined together in a little voltaic arrangement, in a manner far more important than the powerful one you see here, because in nature these minute actions are going on for ever, and are of great and wonderful importance in the precipitation of metals and formation of mineral veins, and so forth. These actions are not for a limited time, like my battery here, but they act for ever in small degrees, accumulating more and more of the results.

I have here given you all the illustrations that time will permit me to show you of chemical affinity producing electricity, and electricity again becoming chemical affinity. Let that suffice for the present; and let us now go a little deeper into the subject of this chemical force, or this electricity—which shall I name first—the one producing the other in a variety of ways. These forces are also wonderful in their power of producing another of the forces we have been considering, namely, that of magnetism, and you know that it is only of late years, and long since I was born, that the discovery of the relations of these two forces of electricity and chemical affinity to produce magnetism have become known. Philosophers had been suspecting this affinity for a long time, and had long had great hopes of success—for in the pursuit of science we first start with hopes and expectations; these we realise and establish never again to be lost, and upon them we found new expectations of further discoveries, and so go on pursuing, realising, establishing, and founding new hopes again and again.

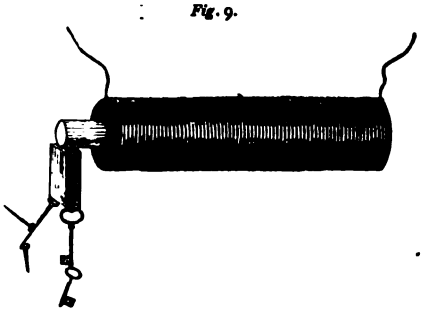
Now observe this: here is a piece of wire which I am about to make into a bridge of force, that is to say, a communicator between the two ends of the battery. It is copper wire only, and is therefore not magnetic of itself. We will examine this wire with our magnetic needle (*fig.* 8.), and though connected with one extreme end of the battery, you see that before the circuit is completed it has no power over the magnet. But observe it when I make contact; watch the needle, see how it is swung round, and notice how indifferent it becomes if I break contact again; so you see we have this wire evidently affecting the magnetic needle under these circumstances. Let me show you that a little more strongly. I have here a quantity of wire which has been wound into a spiral, and this will affect the magnetic needle in a very curious manner, because, owing to its shape, it will act very like a real magnet. The copper spiral has no power over that magnetic needle at present, but if I

Fig. 8.



cause the electric current to circulate through it, by bringing the two ends of the battery in contact with the ends of the wire which forms the spiral, what will happen? Why one end of the needle is most powerfully drawn to it; and if I take the other end of the needle it is repelled; so you see I have produced exactly the same phenomena as I had with the bar magnet,—one end attracting and the other repelling. Is not this then curious to see that we can construct a magnet of copper? Furthermore, if I take an iron bar, and put it inside the coil, so long as there is no electric current circulating round, it has no attraction,—as you will observe if I bring a little iron filings or nails near the iron. But now if I make contact with the battery they are attracted at once. It becomes at once a powerful magnet, so much so that I should not wonder if these magnetic needles on different parts of the table pointed to it. And I will show you by another experiment what an attraction it has. This piece and that piece of iron and many other pieces are now strongly attracted (*fig.* 9.), but as soon as I break contact the

Fig. 9.

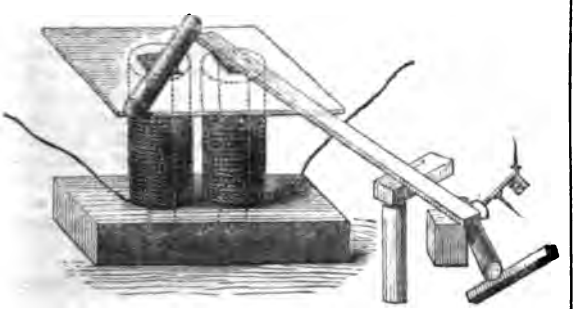


power is all gone and they fall. What then can be a better or a stronger proof than this of the relation of the powers of magnetism and electricity? Again here is a little piece of iron which is not yet magnetised. It will not at present take up any one of these nails; but I will take a piece of wire and coil it round the iron (the wire being covered with cotton in every part so that it does not touch the iron), so that the current must go round in this spiral coil; I am in fact preparing an *electro-magnet* (we are obliged to use such terms to express our meaning, because it is a magnet made by electricity,—because we produce by the force of electricity a magnet of far greater power than a permanent steel one). It is now completed and I will repeat the experiment which you saw the other day, of building up a bridge of iron nails; the contact is now made and the current is going through; it is now a powerful magnet; here are the iron nails which we had the other day, and now I have brought this magnet near them they are clinging so hard that I can scarcely move them with my hand, (*fig.* 10.) But when the contact is

Fig. 10.

broken, see how they fall. What can show you better than such an experiment as this the magnetic attraction with which we have endowed these portions of iron? Here again is a fine illustration of this strong power of magnetism. It is a magnet of the same sort as the one you have just seen. I am about to make the current of electricity pass through the wires which are round this iron for the purpose of showing you what powerful effects we get. Here are the poles of the magnet; and let us place on one of them this long bar of iron. You see as soon as contact is made how it rises in position (*fig.* 11.); and if I take

Fig. 11.



such a piece as this cylinder, and place it on, woe be to me if I get my finger between; I can roll it over, but if I try to pull it off, I might lift up the whole magnet, but I have no power to overcome the magnetic power which is here evident. I might give you an infinity of illustrations of this high magnetic power. There is that long bar of iron held out, and I have no doubt if I were to examine the other end I should find that it was a magnet. See what power it must have to support not only these nails but all these lumps of iron hanging on to the end. What then can surpass these evidences of the change of chemical force into electricity, and electricity into magnetism? I might show you many other experiments whereby I could obtain electricity and chemical action, heat and light from a magnet, but what more need I show you to prove the universal correlation of the physical forces of matter, and their mutual conversion one into another?

And now let us give place as juveniles to the respect we owe to our elders; and for a time let me address myself to those of our seniors who have honoured me with their presence during these lectures. I wish to claim this moment for the purpose of tendering our thanks to them, and my thanks to you all for the way in which you have borne the inconvenience that I at first subjected you to. I hope that the insight which you have here gained into some of the laws by which the universe is governed, may be the occasion of some amongst you turning your attention to these subjects; for what study is there more fitted to the mind of man than that of the physical sciences? And what is there more capable of giving him an insight into the actions of those laws, a knowledge of which gives interest to the most trifling phenomenon of nature, and makes the observing student find

"—— tongues in trees, books in the running brooks,
Sermons in stones, and good in everything."

HANOVER SQUARE ROOMS — *Feb.* 13. 1860.

Chemical Properties of Milk.

On Monday Evening, Feb. 13, a small party of ladies and gentlemen (the latter mostly medical men) attended at the Hanover-Square Rooms, to hear a paper read *On the Comparative Chemical Properties of Human and Animal Milks considered in relation to some Physiological Facts.* Unfortunately the paper offered but little which could come within the province of an exclusively chemical journal, and therefore calls for no extended notice from us.

The object of the authoress (a benevolent lady, who has devoted a great deal of attention to the subject) was to show that when children are brought up by hand, animal milks form but imperfect substitutes for the natural aliment. Cow's milk alone did not contain enough of the combustible or heat giving elements, more of which was needed by weak infants who had not the advantage of the warmth obtained by lying at the breast. She therefore recommended the addition of one sixth or one eighth of vegetable food to the cow's milk. Well cooked bread food or baked flour might be made proper, but if carelessly prepared it was very prejudicial. In the Paris hospitals when the sick infants were withdrawn from the breast and fed upon arrowroot or rice they almost all died; and upon examination their intestines were found lined with undigested starch. It was particularly important that infants' food should be well cooked. The great object of the paper, however, was to insist that nothing could be found which would perfectly replace the mother's milk. In all milks, the authoress stated, there exists an essence, quality, or property — beyond the power of analytical chemistry to separate or distinguish, but no less certainly present — which gives to each a distinctive characteristic, and fits it only for the nourishment of its kind. Even the milk of individuals differed in some subtle ingredient, as is shown by the instinctive aversion which infants sometimes show to particular nurses, whose breasts they absolutely refuse to take.

Dr. Druitt (who occupied the chair) afterwards addressed the meeting on the importance of the subject, and the Superintendant Registrar of Marylebone read some statistics showing the enormous mortality of children under four years of age, 24 per cent. of the whole number dying in the first year. Many of the deaths were directly ascribed to the want of breast milk and improper food, and no doubt a very large proportion of the rest might be traceable to the same cause. The deaths of illegitimate children in their first year he showed was double that of other infants. They were generally put out to nurse with old women, who fed them upon ordinary oatmeal.

Dr. Routh said he did not concur in all that was stated in the paper. Nature intended infants to live entirely on animal food — even the young of graminivorous animals were for a time, until the teeth were developed, nourished on an exclusively animal diet. The offspring of birds were at first fed with larvæ and other animal matters collected by the mother. He believed that much of the excessive mortality was caused by vegetable food. Bread food he considered especially bad — opium was as innocent, and was less troublesome. The effect of alum, which nearly all bread contains, is to fix phosphoric acid in a perfectly insoluble form, and thus to deprive the infant of an ingredient essential for its nourishment. Another objection to the use of vegetable food, was the absence of chloride of potassium, a salt which was absolutely required for the progress of the cell-growth. When teeth are formed vegetable food may be used with advantage. Before starch can become nutritious it must be converted into sugar, and infants at an early age have no salivary glands to supply the ferment necessary to effect the conversion. Cows and goats fed exclusively upon beet root, the doctor said, produced milk exactly like the human secretion, and he recommended that experiments on infantine nutrition should be tried at the Foundling Hospital.

Mr. Harry Lobb said he had introduced a short time ago a *perfect* milk, which was prepared as follows: — dissolve a teaspoonful of sugar of milk in two ounces of boiling water, and then add one ounce of cow's milk, with a teaspoonful of cream. Thinking that after the publication of this paper a great demand for sugar of milk would arise, he ordered *a ton* of the substance from Switzerland; but only two medical men had recommended his milk, and although he had sold a little to the homœopaths, the greater part of his sugar of milk remained on his hands!!

Mr. Ballard and Dr. Druitt afterwards addressed the meeting — but their observations were entirely medical. A vote of thanks to the lady was passed accompanied by a request that she would publish the paper which had been read.

NOTICES OF BOOKS, PATENTS, &c.

Stories of Inventors and Discoverers in Science and the Useful Arts. A Book for Old and Young, by John Timbs, *F.S.A.* London. 1859.

Timbs is nothing to criticise in a book of this kind. Usually happy in the selection of a subject, Mr. Timbs always writes a readable and instructive book on every matter which he takes in hand. The present volume is no exception to this rule. It contains sixty stories of inventors from Archimedes to Brunel, and includes a notice of most of the discoveries in science and the useful arts down to the invention of the electric telegraph. We might fill a number of our paper with interesting extracts, but can only find room for one or two. No doubt our readers would like to know something of the history of Prince Rupert's drops (as they are called), which Dr. Faraday exhibited at his lecture on "Cohesion." (See page 67 Chemical News.)

"These philosophical toys take their English name from having been first made known in England by Prince Rupert, and not from his having invented them as commonly supposed. The drops were first brought to England in 1660, and in the proceedings of the Royal Society occurs this entry:

"'Aug. 14. Sir Robert Moray brought in glass drops, an account of which was ordered to be registered.'

"Accordingly, the first volume of the register book contains a very long account of them and their manufacture. They were so well known when *Hudibras* was written as to be used by Butler in popular illustration. In part ii. canto 2 we have:

"'Honour is like that glassy bubble
That finds philosophers such trouble:
Whose least part crack'd, the whole does fly,
And wits are cracked to find out why.'

"M. Rohalt in his *Physics* calls the drop a kind of miracle in nature, and says:

"'Ed. Clark lately discovered and brought it hither from Holland, and which has travelled through all the universities in Europe, where it has raised the greatest curiosity, and confounded the reason of the greatest part of the philosophers.'"

The drops have long since ceased to puzzle the philosophers, but they remain as great curiosities as ever.

We have seen the engineers and philosophers at fault with regard to steam navigation and railroads, and it seems they were no less mistaken in their opinion about the practicability of safely lighting the streets with gas. Soon after the establishment of the National Light and Heat Company in 1810, an extensive explosion took place on their premises in the Horseferry Road, and a committee of the Royal Society was, at the request of government, appointed to investigate the matter.

"They met several times at the gas works to examine the apparatus, and made a very elaborate report, in which they stated as their opinion, that if gas lighting was to become prevalent, the works ought to be placed at a considerable distance from all buildings; and that the reservoirs should be small and numerous, and always separated from each other by mounds of earth or strong party walls. This committee was composed of Sir Joseph Banks, Sir C. Blagden, Col. Congreve, Mr. Lawson, Mr. Rennie, and Dr. Young. In the company's application to Parliament, one of their witnesses, Mr. Accum the chemist, was bitterly ridiculed by Mr. Brougham, F.R.S.; and Sir Humphry Davy asked if it were intended to take the dome of St. Paul's for a gasometer! In short, as Dr. Arnott remarks, 'Davy, Wollaston, and Watt, at first gave an opinion that coal gas could never be safely applied to the purpose of street lighting.' However, the invention progressed, and in 1822 St. James's Park was first lighted with gas."

The London companies, we are informed, have now 2000 miles of main pipes, and storage for ten million cubic feet of gas. Both "old and young" will find much that will interest them in Mr. Timbs's book.

Improvements in obtaining or extracting Quinine and the Principal Organic Alkalies. (A communication.) W. Clark.

A decoction of the bark in dilute hydrochloric or sulphuric acid is obtained; an alkali or alkaline carbonate is then added until precipitation ceases. The liquor holding the precipitate in suspension is then boiled, and a certain quantity of solid fatty acids added; these acids then melt and form a layer on the surface with which all parts of the liquid under the influence of ebullition come in contact successively, and the quinine being dissolved in the water combines with the fatty acids and forms with it a perfectly insoluble soap. After a certain time the precipitate becomes of a blackish colour. The liquor is then allowed to cool, when the fatty acids become solidified on the surface, and are removed in the form of a cake and then boiled with distilled water for removing any impurities with which it may be mechanically combined. This is continued until the fatty matter yields nothing more to the pure water; it is then boiled in water acidulated with sulphuric acid, and the excess of acids subsequently saturated by an alkali. Some dark matters will be precipitated, and after filtration a crystallised block of sulphate of quinine will be obtained by cooling, which block may be purified as usual.

CORRESPONDENCE.

Poison Labels.

To the Editor of the Chemical News.

Sir,—As the necessity for the sale of many poisonous substances is I think admitted by all who are familiar with the requirements of the public, it is desirable, as much as possible, to make them fully aware of the risk that attends their sale; with that end in view, I have had the subjoined label printed, and attach it to every packet of poison sold, such as oxalic acid, red and white precipitates, &c.

> CAUTION!!!
>
> As the sale of all Poisonous Substances is attended with great risk, it is earnestly requested that this preparation may be kept away from Children, and not placed where Food, &c. is deposited. —— will always supply a label with the word "POISON" on it to affix to bottles, &c.

I venture to send this to you, that if there is any novelty in the idea, it may be at the service of others who will be able to improve upon it.

X.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

Oxides of Cerium, and the Yellow and Red Sulphates.—Cerium, according to Rammelsberg[1], may be obtained from lanthanum and didymium perfectly pure by the process of M. Hermann, which consists in precipitating the subsulphate of ceroso-ceric oxide by means of water.

The *protoxide of cerium*, CeO, is obtained by heating the carbonate or oxalate in a current of pure hydrogen. It is a bluish-grey powder, which, exposed to air, becomes ceroso-ceric oxide, and takes a yellow colour: its hydrate is white.

Ceroso-ceric oxide, $CeO.Ce_2O_3$, is procured by calcining in the air either the carbonate, oxalate, or cerous nitrate. It is yellowish-white, with a slightly red tint, becoming yellow for a time when heated, and only dissolves in concentrated sulphuric acid, forming an orange coloured liquid. Hydrogen reduces it to cerous oxide. Neither calcination in

[1] *Journal für Praktische Chemie*, Bd. lxxii. s. 67, 1859.

oxygen nor fusion with nitre will oxidise it further. Its hydrate contains 3 atoms of water, and is formed when chlorine is passed into a solution of potash, holding in solution the hydrate of cerous oxide.

From the orange coloured solution of ceroso-ceric oxide in sulphuric acid the following salts may be obtained;

The *brown-red or orange sulphate* (*a*), crystallised in hexagonal prisms, which contains $3(CeO.SO_3) + Ce_2O_3 3SO_3 + 18\,HO$. This salt is decomposed by water, separating into a sulphur-yellow basic salt, and giving with potash a greyish-red precipitate, which contains $3CeO + Ce_2O_3$, which becomes yellow in the air, changing into $CeO.Ce_2O_3$, and attracting a small quantity of carbonic acid.

A *yellow sulphate* (*b*) irregularly crystallised, which contains $CeO.SO_3 + Ce_2O_3.3SO_3 + 8$ aq. With water it behaves like salt (*a*).

The *basic ceroso-ceric sulphate*, formed by the action of water on the preceding salts, constitutes a clear yellow precipitate, whose composition may be represented by the formula

$$2(CeO.SO_3) + 2(Ce_2O_3)\,SO_3 + 6\text{ aq.}$$

Calcined at a bright red heat all these sulphates leave ceroso-ceric oxide. When solutions of the red-brown ceroso-ceric sulphate (*a*) and sulphate of potash are mixed a yellow precipitate is formed, constituting a mixture of double salts.

With sulphate of ammonia a crystalline granular precipitate is formed, but at the same time beautiful orange crystals may be obtained, whose composition answers to the formula

$$9(NH_4O.SO_3) + [CeO.SO_3 + 2(Ce_2O_3\,3SO_3)] + 12\text{ aq.}$$

Calcined, these double ammoniacal salts leave ceroso-ceric oxide.

The mean of four analyses of *cerite* gave as the composition:

		Oxygen.
Silica	19·18	9·96
Protoxide of cerium	64·55	11·17
Oxides of lanthanum and didymium	7·28	
Lime	1·35	
Protoxide of iron	1·54	
Water	5·71	5·09
	99·61	

These proportions are very nearly expressed by the formula

$$\left.\begin{matrix}CeO\\LaO.DiO\\CaO.FeO\end{matrix}\right\}^{2} SiO_3 + \text{aq.}$$

On the Isomorphism of the Oxides of Tin, Silica, and Zirconia.—After the last experiments of Marignac, who has proved the isomorphism of the fluostannates and fluosilicates, it seems certain that the correct formula for silica is SiO_2. It appears probable also that zirconia is constituted in a similar manner, and may be represented by the formula ZrO_2. This has led M. G. Rose[2] to regard zirconium as a combination of two isomorphous substances, zirconic acid, ZrO_2, and silicic acid, SiO_2, capable of crystallising separately in the right prismatic type with square base. Oxide of tin closely approaching by its form and angles, M. G. Rose concludes that the oxides of tin, silica, and zirconium are isomorphous.

II. ORGANIC CHEMISTRY.

Products of the Oxidation of Legumine.—From legumine extracted from lentils and submitted to the action of bichromate of potash and diluted sulphuric acid, Froehde[3] has obtained by distillation an acid liquid having the odour of hydrocyanic acid, which does not give with the salts of silver the characteristic reaction of aldehydes. This liquid contains a trace of formic acid. By distilling it again there may be separated one portion having an etherial aromatic odour, and another portion having a strong acid reaction. From this last, by proper treatment, may be obtained benzoic, valerianic, butyric, acetic, propionic, caproic, and perhaps caprylic acids.

Oxalantine, a new derivative of Uric Acid.—It is known that alloxan and parabanic acid have some analogous properties. In contact with alkalies both fix two atoms of water, and are converted into acids:

$$\underbrace{C_8H_2N_2O_8}_{\text{Alloxan.}} + 2\,HO = \underbrace{C_8H_4N_2O_{10}}_{\text{Alloxanic acid.}}$$

$$\underbrace{C_6H_2N_2O_6}_{\text{Parabanic acid.}} + 2\,HO = \underbrace{C_6H_4N_2O_8}_{\text{Oxaluric acid.}}$$

When boiled with alkalies they fix four atoms of water and break up, one into urea and mesoxalic acid, the other into urea and oxalic acid:

$$\underbrace{C_8H_2N_2O_8}_{\text{Alloxan.}} + 4\,HO = \underbrace{C_2H_4N_2O_2}_{\text{Urea.}} + \underbrace{C_6H_2O_{10}}_{\text{Mesoxalic acid.}}$$

$$\underbrace{C_6H_2N_2O_6}_{\text{Parabanic acid.}} + 4\,HO = \underbrace{C_2H_4N_2O_2}_{\text{Urea.}} + \underbrace{C_4H_2O_8}_{\text{Oxalic acid.}}$$

On the other hand, by the action of reducing agents on alloxan, alloxantine is formed. The corresponding term also exists in the parabanic acid series. It is a new body, to which the name *oxalantine* has been given.

$$2\underbrace{C_8H_2N_2O_8}_{\text{Alloxan.}} + 2\,H = \underbrace{C_{16}H_4N_4O_{14}}_{\text{Alloxantine.}} + 2\,HO$$

$$2\underbrace{C_6H_2N_2O_6}_{\text{Parabanic acid.}} + 2\,H = \underbrace{C_{12}H_4N_4O_{10}}_{\text{Oxalantine.}} + 2\,HO$$

Sulphuretted hydrogen does not act on parabanic acid; but if dilute hydrochloric acid and a little zinc are added to parabanic acid, hydrogen is slowly disengaged, and there is formed a white crystalline powder, which is a compound of oxalantine with oxide of zinc. This powder is washed with water and decomposed by sulphuretted hydrogen. The solution properly concentrated furnishes oxalantine in the form of a crystalline crust. It is but slightly soluble in water, and is almost insoluble in alcohol and ether. The aqueous solution is slightly acid. Heated with oxide of mercury or nitrate of silver it remains perfectly transparent; but when ammonia is added, reduction immediately takes place. Heated with moderately strong nitric acid or with peroxide of lead oxalantine undergoes no oxidation. Its composition is expressed by the formula $C_{12}H_4N_4O_{10} + 2\,HO$, in which we admit two equivalents of water of crystallisation; but this water cannot be got rid of by heat without altogether decomposing the body.

Oxalantine dissolves easily in caustic and carbonated alkalies, in the latter with effervescence. By evaporating these solutions the author[4] thinks he has obtained oxalurates, but he has not established the point with certainty.

III. CHEMICAL ANALYSIS.

New Method of detecting Nitric Acid in the Dry Way.—Professor W. Stein[5] gives a method for detecting nitric acid in the dry way when combined with bases. When heated the nitrates of potash and soda give off oxygen, and form fixed nitrites. The nitrates of baryta, strontia, and lime, together with those of magnesia, alumina, and the heavy metals, when heated give up the nitric acid, which is split into oxygen and nitrous acid. As however we do not always know with what base the acid may be combined, the author recommends the following mode of testing. He heats the substance in a test tube either with bisulphate of potash or oxide of lead, placing in the upper end of the tube a strip of filtering paper moistened with a slightly acid solution of pure sulphate of iron. If the nitrates are present only in so small a quantity that the nitrous vapour is not itself perceptible, the paper becomes of a yellowish-brown colour. In this way the author discovered the 2000th part of nitric acid

[2] *Poggendorff's Annalen der Physic und Chemie*, Bd. cvii. s. 602.
[3] *Journal für Praktische Chemie*, Bd. lvii. s. 290.
[4] M. H. Limpricht, *Ann. der Chem. und Pharm.* cxi. p. 193.
[5] *Polytech. Centralblatt*, p. 1624, 1859.

in a mixture, which by the usual moist way would have been impossible. The process is particularly applicable for the detection of nitric acid in spring waters. In applying the test it is necessary to guard against heating the paper. In the presence of chlorides the employment of bisulphate of potash is objectionable, because the liberated chlorine colours the paper by forming chloride of iron. The presence of protoxide of iron or much organic matter in the substance also interferes with the bisulphate of potash test.

Estimation of Free Nitric Acid.—Schaffgotsch[6] points out that free nitric acid may be estimated in the form of nitrate of ammonia, a salt of perfectly constant composition, which can be easily weighed in a covered crucible after being dried at 240° F.

Separation of the Sulphates of Lead and Baryta.—Hyposulphite of soda dissolves sulphate of lead, and may be used to separate this salt from the sulphate of baryta. To effect this separation a concentrated solution of the hyposulphite must be added to the mixture of the two salts, and the whole gently warmed, taking care that the temperature does not exceed 68°; at a higher temperature sulphite of lead is formed, which is insoluble in the hyposulphite.

The residue of sulphate of baryta is carefully washed and weighed; to control the results the lead in the hyposulphite may be estimated.

SCIENTIFIC NOTES AND QUERIES.

Water-purifying Patents. — Sir, — While I have no desire to continue any controversy with your correspondent Mr John Horsley, of whom I know nothing, I trust, notwithstanding your editorial note of last week, that you will afford me room to say, that even (were the peroxide of manganese mentioned, as he says it is, "in book after book," in connection with the purification of water, yet that fact would not in the slightest degree invalidate my patent of 1857. At the same time it seems somewhat odd that the correspondent who told your readers a week or two back that he had "found the peroxide of manganese to be a most invaluable agent, not only in decolorising, but deodorising water," should now, on finding himself anticipated, inform the same readers, that the fact is to be "found in book after book."

What other could have been his object in thus gratuitously informing chemical readers of what he had "found," if it were not to leave them to infer the discovery to be his own? Certainly I thought so, otherwise I should not have replied to his letter.

In scientific literature it is an acknowledged rule, that when a writer, be he who he may, says in connection with an experimental investigation that "I have found" such and such to be so — without any other authority being mentioned, he intends it to be implied that *he*, the writer, has discovered the fact in question.—*Thomas Spencer.*

A newly imported Article from Japan. — Sir, — I enclose you a specimen of the above, which is now in the London docks. In appearance it is not unlike some kinds of French isinglass, is soluble in boiling water to the extent of four fifths, but requires longer boiling, and a much larger quantity of water than ordinary isinglass, which it was represented to be. The resulting jelly is neither so bright nor so firm or tough as that made from genuine glass, nor will it bear much working with a spoon, which separates interstitial water.

Chemical tests go to prove that it is entirely *destitute* of that peculiar principle known as "animal gelatine" upon which the commercial value of isinglass depends.

The *incineration* test, however, proves that the substance in question is *not* animal matter at all, but a preparation of pectin, or vegetable jelly, analogous to Carrageenin, which has been rolled out into a sheet form and dried: as such it may be useful as a diet and demulcent for invalids, being nicer and cleaner looking than carrageen or Irish moss.

Fifty grs. of the substance yielded four grains of white ash, which nearly all dissolved in distilled water, and showed the presence of chlorine, sulphuric acid, lime, and soda. — *John Horsley, F.C.S*

[6] *Poggendorff's Annalen der Physic und Chemie*, cviii. p. 64.

MISCELLANEOUS.

Medical Stores for the Navy.—On Tuesday evening last, Lord C. Hamilton asked the Secretary of the Admiralty whether the attention of the Board had been directed to the quality of the wine supplied to the Navy for medical purposes, it having been described as unfit for the use of invalids, although exempt from duty; and also whether he could give an assurance to the House that the drugs supplied to the Navy are not of an equally adulterated and deleterious description. Lord C. Paget said the drugs were supplied from Apothecaries' Hall, and were necessarily of the best quality. As regarded the wine, they had not received complaints from any of the ships, but as the statement of the Chancellor of the Exchequer had produced some sensation, he would direct inquiries to be made on the subject.

Treaty with France.—In the treaty just concluded with the Emperor of the French, her Majesty engages to recommend to Parliament to enable her to abolish the duties of importation on the following articles: — Sulphuric and all other mineral acids; lucifers of every description; percussion caps; corks; articles covered with copper by galvanic process; manufactures of lead, enumerated or not enumerated; sulphate of quinine and salts of morphine.

His Majesty the Emperor of the French engages, that on the following articles of British production, imported from the United Kingdom into France, the duties shall in no case exceed thirty per cent. *ad valorem*, the two additional decimes included: —Chemical productions, enumerated or not enumerated; extracts of dye woods; garancine; common soap of every description, and perfumed soaps.

With respect to chemical productions, of which salt is the basis, the excise or inland duties shall be added to the amount of the above specified duties.

The Chancellor of the Exchequer also proposes to make the following articles free of duty: — Almonds; cassia lignea; chloroform; cinnamon; cloves; cocculus indicus; daguerreotype plates; extracts, as denominated in the tariff; ginger; glass of all kinds; grains (Guinea and of paradise); liquorice paste, powder, and juice; mustard; nux vomica; opium; pimento; quassia; salicine; carraway seeds; stearine; and tallow.

Until the 31st of March 1861, the duty on corks to be: — Ready made, 3*d.* the lb.; squared for rounding, 4*s.* the cwt.

The Adulteration of Food Bill passed the second reading in the House of Commons on Wednesday last.

Physician's Cane.—An enterprising American has taken out a patent for the above article. It consists in having the cane hollow or formed of a tube closed at its bottom and having a semi-tube attached to the knob or handle, the said semi-tube fitting within the cane and allowed to move freely in and out of it, and forming a receptacle for vials containing medicine. The invention is chiefly designed for country physicians who are compelled to carry medicines with them.

Liquid Glues.—Dissolve 33 parts of best glue on the steam bath in a porcelain vessel, in 36 parts of water. Then add gradually, stirring constantly, 3 parts of aqua fortis, or enough to prevent the glue from hardening when cool. Or dissolve 1 part of powdered alum in 120 parts of water, add 120 parts of glue, 10 of acetic acid and 40 of alcohol, and digest. — *Druggist's Circular.*

ANSWERS TO CORRESPONDENTS.

Inops.—We will endeavour to obtain an authoritative answer to your question.

Dr. Meyer's communication is in the press.

J. B. E.— x and y are intended to represent any whole number whatever. In the formula referred to

$$x(NH_4Cl+KNO_6)=(x-y)(NH_4Cl+KNO_6)+y(NH_4NO_6+KCl)$$

x may represent any number provided y is a lower number.

Œlas.—1. We do not know. 2. Piesse's.

Pyrometer.—To convert centigrade degrees into Fahrenheit degrees, multiply by 9, divide the product by 5, and add 32: to convert Fahrenheit into centigrade degrees, substract 32, multiply by 5, and divide by 9. To reduce the degrees of Reaumur to Fahrenheit, multiply by 9, and divide by 4. Such a plan as our correspondent suggests is under consideration.

P. M. Henschikoff— *W. M.* (Manchester) —*Excelsior* —*B.*— *Phosphate* —received. Answers next week.

Book received.—*On the Sewerage of Towns as it affects British Agriculture*, by Mr. Alderman Mechi.

*** All *Editorial Communications* are to be addressed to the Editor; and *Advertisements* and *Business* communications to the Publisher, at the Office, 12 and 13 Red Lion Court, Fleet Street, London. E. C.

THE CHEMICAL NEWS.

VOL. I. No. 12. — February 25, 1860.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Researches on the Organo-metallic Radicals, by M. AUGUSTE CAHOURS.[1]

CERTAIN bodies of a more or less complex nature which behave exactly in the same way as simple substances, have received the name of radicals. These bodies have particularly fixed the attention of chemists since the publication of Bunsen's work on Cacodyle, and the researches of Frankland on Zinc-ethyl. I have resumed the study of these interesting products, which I commenced some years ago in concert with M. Riche, and I now proceed to give some account of the remarkable part which they play with regard to oxygen, chlorine, sulphur, &c.

One simple body cannot unite with others in all imaginable proportions: daily experience in fact teaches us that two bodies can only form a very limited number of combinations, and further that when this number exceeds two or three, they have in general but little stability. Such is the case with the compounds of chlorine with oxygen.

Among the various compounds which two simple bodies can form by their mutual union, there is always one which possesses more stability than the others, and towards which these different products necessarily converge. Thus for the alkaline metals the most stable grouping is represented by the general formula RX, while for the salts of iron and its analogues the form is R_2X_3, and for tin and titanium RX_2.

But the greater or less stability of such a grouping is evidently relative only to particular circumstances, since every time that we place under determined conditions the different compounds a body is susceptible of forming, they will invariably be brought to that particular form which alone is possible under these conditions. Everyone knows, for example, that of all the combinations which phosphorus can form with oxygen, the most stable is phosphoric acid. We can under special influences combine phosphorus with other proportions of oxygen; but these various compounds will all, under the action of elevated temperatures converge towards the grouping PO_5. As long as the phosphorus has not assimilated the proportion of oxygen necessary to form phosphoric acid, we can add new quantities, and further, in place of a portion of this oxygen, we may put other simple bodies, such as chlorine, sulphur, &c. so as to produce the substances known as oxychloride and chlorosulphide of phosphorus, belonging like phosphoric acid to the grouping PX_5.

When then we bring in contact two simple bodies capable of uniting directly in well-defined conditions, there exists for these bodies a state of saturation presenting an equilibrium, which it is impossible to go beyond. So long as this state of equilibrium is not attained we may keep on adding to the first body a new proportion of the second, and so on until we arrive at the point of saturation. But there are certain bodies which in uniting with others give rise to products having as great and sometimes even a greater tendency to combination than the simple bodies themselves. Such are carbonic oxide, sulphurous acid, &c. which not only absorb new quantities of oxygen with more facility than carbon and sulphur themselves, but which form with chlorine, iodine, &c. compounds corresponding with those which are at the maximum of oxidation. These compounds, which can be separated intact from combinations they may have contracted, and which present all the characters of true simple bodies, have been designated *radicals*.

Every compound may be considered as a molecular system in equilibrium, in which the atoms are attracted one towards another by virtue of more or less powerful affinities. If we replace one or more atoms of one of the elements of the combination, by an equal number of atoms of another substance, we obtain new compounds all presenting the same mechanical arrangement as the primitive product, but whose state of equilibrium will vary according as the reciprocal attractions of the bodies which constitute the new substance are stronger or weaker than those of the original body. It is thus that ammonia can exchange all or part of its hydrogen for chlorine, bromine, iodine, carbon, ethyl, the metals, &c. to form compounds belonging to the same system, but presenting the most variable degrees of stability.

Ammonia resisting perfectly a dull red heat, it is easily explained how it is that chloride of nitrogen is decomposed at temperatures much lower than boiling water, the mutual affinity of chlorine and nitrogen being incomparably weaker than that which induces nitrogen to unite itself with hydrogen.

If we remove an atom from a compound without replacing it, and if the new compound which results from the subtraction presents a certain stability, it is able to fix anew the atom eliminated, and so reproduce the original body, or to combine with any other simple body to form compounds of the same type, playing then the part of a radical. Thus, when ammonia is acted on by carbon at a red heat, we replace 2 atoms of hydrogen by 2 atoms of carbon, and form hydrocyanic acid, a compound of the same type as ammonia. This by reacting on oxide of mercury gives cyanide of mercury, a body presenting the most perfect analogy with it: then, if we subtract the molecule of mercury there remains the compound C_2N, which, to return to the ammonia type, must needs fix different simple bodies, playing with regard to them, sometimes the part of an electro-positive, and sometimes of an electro-negative element. If cyanogen simulates completely the characters of a simple body, it is owing partly to its stability, and partly to its tendency to pass to the maximum of saturation, by assimilating a molecule of various simple bodies, in order to return to the ammonia type from which it was derived.

When methyl, ethyl, amyl, &c. unite with certain simple bodies, they form products whose affinity for oxygen, chlorine, &c. greatly exceeds that of simple

[1] Abridged from the *Annales de Chimie et de Physique*.

bodies for these substances. Zinc, which only absorbs atmospheric oxygen slowly, and which does not act on pure water at the ordinary temperature, effects with extreme violence the decomposition of this liquid, when it is united either with methyl or ethyl, the molecule of the compound dividing itself into zinc, which unites with the oxygen, and into ethyl or methyl which takes the hydrogen to form hydrides. It is the same when magnesium and aluminum are concerned, and with still greater reason in respect to the more electro-positive metals, such as sodium and potassium.

The metals more electro-negative than zinc, such as tin, lead, mercury, can like the preceding, unite with the alcoholic radicals, forming with them compounds which are endowed with a great affinity for oxygen, chlorine, &c.; but these affinities being weaker, it will necessarily happen either that the term of saturation being attained, the compound behaves like an inert substance in regard to these bodies, or the saturation not being satisfied a simple union takes place.

The compounds of methyl or ethyl with the metal separated intact from their new combinations, will necessarily play the part of an elementary substance. The curious properties of these metallic ethylides and methylides which behave exactly like real metals, more electro-positive than the simple metals they contain, have given rise to very legitimate doubts as to the simple nature of the metals themselves, the more so as, up to the present time, science has not registered a single fact which can support the hypothesis of their elementary character.

Methyl or ethyl, when they unite with the electro-negative bodies which are placed at the head of the series of simple bodies (oxygen, chlorine, bromine, iodine, &c.) form very stable and perfectly neutral compounds; but in proportion as we descend the scale and come towards potassium, which stands at the bottom, we obtain compounds less and less stable, and endowed with such strong affinities for those which occupy the upper extremity that a decomposition of the molecule results, with the formation of very simple and stable products.

Intermediately we obtain compounds endowed with strong affinities for oxygen, chlorine, iodine, &c.; which can enter directly into combinations, and be withdrawn from them intact, thus playing the part of true radicals, unless the proportion of methyl or ethyl forming part of these compounds represents the term of saturation, in which case the new molecule is inapt to enter into combinations.

When a simple body froms with various other simple bodies compounds whose term of saturation is represented by the formula AB_x (x being a very simple whole number) experience shows us that we may form with this simple body and the various alcoholic radicals, (methyl, ethyl, &c.) compounds of different states of saturation. As long as the number of molecules of the alcoholic radical which enters into the combination is lower than x, the new compound formed can unite with oxygen, chlorine, &c. and act in the same way as a true radical. Experience likewise teaches that in proportion as the number of equivalents of the alcoholic radical which unites with A is increased, the compound which results is endowed with stronger and stronger affinities for oxygen, chlorine, iodine, &c.; the acid or neutral principles they were originally passing on towards alkalinity in the most decided manner. Arsenic offers in this respect a most striking and instructive example. This body inclines to form two principal groupings: AsX_3, and as $As X_5$. We are able then to form with arsenic and methyl five well-defined bodies, the last being incapable of producing new combinations, because the term of saturation is attained. Now the experiments of MM. Bunsen, Bayer, Landolt, and my own, show that we can form with arsenic and methyl the four compounds, $AsMe$, $AsMe_2$, and $AsMe_3$, and $AsMe_4$. If we place these various compounds in the presence of an excess of oxygen so as to obtain saturated combinations, we shall have:

$As\ MeO_4$
$As\ Me_2O_3$
$As\ Me_3O_2$
$As\ Me_4O$,

which form with water the following compounds:

$As\ MeO_4$, $2HO$,	a bibasic acid.
$As\ Me_2O_3$ HO,	a monobasic acid.
$As\ Me_3O_2$,	an indifferent body.
$As\ Me_4O$ HO,	a strong base, comparable to potash and soda.

The oxygenated combination which occupies the superior term presents strongly acid characters, and the last possesses so much alkalinity as to rival the most powerful bases.

Nitrogen, like arsenic, is capable of forming five perfectly defined groupings, which may be formularised in the following way: NX, NX_2, NX_3, NX_4 and NX_5. With oxygen we can realise these five groupings, the most interesting of which is the term of saturation NO_5. If we replace in these compounds a part of the oxygen they contain with equivalent quantities of chlorine, we obtain chloronitrous and chloronitric acids, whose constitution perfectly corresponds with the nitrous and hyponitric acids from which they are derived.

Contrary to what we observe with oxygen, we are at present able to isolate but one compound of nitrogen with hydrogen. This body, well known to everybody under the name of ammonia, and whose composition is expressed by the formula NH_3, corresponds with the grouping NX_3. This remarkable compound can exchange one or more of its equivalents of hydrogen for an equal number of elementary molecules or even of groupings more or less complex. Ammonia being endowed with basic properties will produce bases by these substitutions if we replace its hydrogen by bodies endowed with analogous chemical functions, while it will produce neutral bodies and even acids if we replace the hydrogen by bodies whose chemical properties are opposed to it. When, for example, the body which is substituted for hydrogen is methyl, ethyl, amyl, phenyl, &c. we obtain bodies which present not only the most complete parallelism of composition, but whose chemical characters so resemble those of ammonia, that the history of these compounds may be deduced from that of ammonia itself. We may easily imagine the chemical functions of the carbides of hydrogen greatly resembling those of hydrogen; and what is most worthy of attention here is, that the alkalinity of these bodies depends upon the number of equivalents of methyl, ethyl, &c. which are substituted. These results become more striking still, when we consider the compounds resulting from similar substitutions effected in phosphuretted hydrogen. Trimethylphosphine (PMe_3) and triethylphosphine (PE_3) can combine with various acids, which phosphuretted hydrogen cannot do. The last body can only unite with hydriodic acid, and then the combination is so unstable that contact with water is sufficient to destroy it.

If we are unable to form any compound of nitrogen and hydrogen corresponding with nitric acid, and consequently to the form NH_5, we know at least a great numbe

which may be considered as belonging to the same type, and which are comprised in the general formula NH_4Y. Thus, for example, dry ammoniacal gas like many carbides of hydrogen, unites directly volume for volume with hydrochloric, hydrobromic, hydriodic acid gas, &c. to form compounds which enter the preceding formula, that is to say, NH_4Cl, NH_4Br, NH_4I, compounds in which some chemists admit the existence of a radical NH_4. This radical has not yet been obtained in a free state, notwithstanding all the attempts which have been made; and it is much more simple to admit that the union of the two bodies brought into contact produces a particular grouping belonging to the type NH_5, which for nitrogen appears to be the saturating point of the combinations it is susceptible of forming.

It is the same with regard to the derivatives of ammonia known under the names trimethylamine, triethylamine, and triamylamine (NMe_3, NE_3, $NAmy_3$), which can fix MeCl, ECl, AmyCl, to form compounds of the same order, in which it would be necessary to admit the existence of new radical derivatives of ammonium, which have no more been isolated than ammonium itself. Is it not then more simple to admit that nitrogen as well as its congeners is capable of forming various definite combinations whose term of saturation is the form NX_5.

Supposing that some day the term NH_4 should be isolated, which is not unlikely; it is more than probable that like methyl and ethyl, it will furnish under the influence of chlorine and bromine substitution products, and not chlorides and bromides like potassium and sodium. If ammonia does not fix directly two equivalents of oxygen, chlorine, bromine, &c. to form compounds which enter the preceding group, and if it is the same with its derivatives NMe_3, NE_3, $NAmy_3$, it is owing in part to the great alkalinity of these products, to the great affinity of chlorine and bromine for hydrogen, and to the feeble tendency of nitrogen to combination. It is not the same with the corresponding compounds of arsenic and phosphorus. The products PMe_3, PE_3, $AsMe_3$, AsE_3, can absorb two equivalents of oxygen, sulphur, or chlorine: hence the differences we observe between nitrogen and its congeners, although these bodies are allied by very strict analogies.

As the metals form definite combinations with oxygen, chlorine, sulphur, &c. we might suppose with reason that the same bodies would form similar compounds with methyl, ethyl, &c. The beautiful researches of Frankland have made known the methylide and ethylide of zinc, compounds belonging to the form ZnX. Wanklyn has since shown us that the alkaline metals can form analogous combinations, but these are so unstable that at present we only know them united with the methylide and ethylide of zinc. Brought into contact with water, all these compounds immediately decompose, forming oxides of the metals and hydrides of methyl and ethyl, a result easy to understand when we remember that these various products represent saturated compounds containing elements endowed with strong affinities for the elements of water, and consequently very apt to bring about its destruction, entirely decomposing themselves. The ethylide of zinc cannot act as a radical any more than the alkaline ethylides, since they represent the most stable grouping which these metals are capable of forming.

A great number of metals have the power of acting on the iodides of methyl and ethyl in closed tubes at temperatures varying from 120° to 200° C. In some cases we obtain free ethylides, as in the case of magnesium; in others, and especially with tin, we obtain sometimes ethylides, and sometimes combinations of these products with iodine. In the course of my labours I have verified the exactness of most of the facts announced by my predecessors; I have had the honour to register some new facts, and I have especially endeavoured to connect the constitution of these curious compounds with the well known combinations the metals form with oxygen, chlorine, and their analogues.

(*To be continued.*)

TECHNICAL CHEMISTRY.

On the Manufacture of the Carbon Elements for Bunsen Batteries, by JOHN YOUNG, *Manager of the Gas-works, Dalkeith.*[1]

THE advantages attending the use of the Bunsen Battery as a powerful source of electric action has led to its very general adoption, especially in those experiments of a more brilliant character. The peculiar construction of this battery consists in substituting for platinum, carbon of that condition found in the interior of gas-retorts. The difficulty of procuring carbon of this sort, and especially of giving it a proper form when obtained, led to the series of experiments and their results which form the subject of this communication.

Hitherto the supply of prepared carbons has almost exclusively been furnished to this country from the Continent; and so far as they have come under my observation they were made from the retort carbon above mentioned. The precariousness of a supply from this source, and the fact of its being dependent for its continuance upon an evil which gas-engineers are trying all means to overcome, suggested the propriety of finding some compound, and mode of treating it, which would render us equally independent of foreign aid, and that period in the history of gas-lighting when the engineer has attained his object. During the spring of last year these experiments were entered upon; and for several weeks at first occupied my whole attention, and at brief intervals during the summer were resumed. In the first outset we were entirely guided in our procedure by the information of the composition and treatment of the carbons by Professor Bunsen, as given in several works on electrical science; but whether the material used by me, or the mode of treatment differed from that of the Professor we do not know, but the results in our hands were most unsatisfactory indeed. The prescribed composition used by the Professor is "coke and coal in fine powder, heated together in an iron mould, thus forming a mass of solid carbon of the required form. To give greater solidity, they were plunged into a syrup of sugar, afterwards dried, and then submitted to an intense heat in covered vessels." These instructions are apparently plain enough, unencumbered by detail, and would indicate, by their brevity, that the *solid mass of carbon* was so sure of being obtained that more minute instructions were totally unnecessary. In our experiments we employed the finest pieces of Newcastle coke in powder and the finest English caking coal, and followed the recipe with great care. We used (1) cold moulds, afterwards heating them carefully; and (2) red-hot moulds, and packed in the composition in a fused state; and yet the four weeks in which we were so occupied were characterised by one series of failures, during which we had wasted large quantities of sugar, besides less

[1] Transactions of the Royal Scottish Society of Arts.

valuable materials, without receiving a single hint that we were proceeding in the right direction; and not until a partially new process was entered upon did hopes arise that we would ever attain our object. The carbon elements so obtained were either loose and friable, or altogether in a state of powder, or so full of cracks and fissures, when an excess of coal was used, that in either case they were useless. Some of the best we endeavoured to finish; but after repeated soakings in the syrup of sugar, we could with difficulty produce them of sufficient density; and, when attainable, only at such expense as precluded competition in price with those already in the market.

Starting anew, and availing ourselves of the varieties of coke within reach, and trusting to our own observations for guidance, we entered upon a new series of experiments with different kinds of coke, mixed in various proportions, and differently treated. Among failures, we also had hints of success, and from noting the changes by which these favourable hints had been furnished, we were able to proceed under more cheering prospects. The results of these experiments were, that the coke from the Marquis of Lothian's parrot coal, as left in the gas retort, was best. What peculiarity in this coke should make it superior we cannot say, unless it be the small amount of ash that it contains; but when used by us, it was always covered by a peculiar glistening, silvery deposit of carbon from its own gas. The amount of ash in the coke we found to be less than 7 per cent.

After many trials, we obtained the best results from the following mixture and mode of treatment — viz. 64 per cent. by weight of coke powder, and 36 per cent. of English caking coal in powder, well mixed, and moistened with a solution of sugar or starch, until the mass, when pressed in the hand, retained its form. When starch was used, it was in the form of mucilage; and when syrup of sugar was used, it was composed of one part of sugar to one and a half of water. The prepared composition was pressed very hard into moulds of the required form, and when taken from the mould the cakes were set aside to dry. The use of sugar or starch in the composition is to cause the adhesion of the particles of coke and coal powder, so that they retain the form of the mould, and when dry become a hard cake that can be handled, and closely packed into the coking-mould. The part of the process referred to is conducted precisely the same as in the manufacture of ordinary bricks; but the similarity of manufacture goes no further, as all air has to be excluded from the carbons, otherwise combustion ensues, and entirely destroys them. To prevent the action of the air, the coking is done inside a gas retort, into which a small quantity of coal had been introduced to expel the air. The box or mould in which the bricks were packed during the coking contained thirteen carbons at one time. The length of the box was equal to the thickness of the whole thirteen, including plates of iron of ¼ inch thickness, which were placed between them, to prevent the carbons from fusing together. The breadth of the box was equal to the length of the carbons, and the depth equal to the breadth of the carbons. The mould with cover was so constructed, that the encased carbons should be closely clamped up and compressed between the plates while coking. The great tendency that the caking coal has to tumify while in fusion, by the escape of the gas, made this precaution the more necessary; and unless attended to the carbons would have been loose and porous. The box and its contents were in the retort for about one hour and a half, at a bright cherry-red heat; and when taken out were covered over with dry dust until cold, to prevent the air from acting on the carbons through the chinks round the cover. When taken from the box the carbons have a close surface, owing to the iron plates compressing the exuding fused coke. At this stage they have no electrical action, and are entirely dependent upon the subsequent parts of the process for the deposit of carbon to bestow this property. From this point in the manufacture my mode of treatment is new, and depends for the closing of the pores in the coke to the fixed carbon from a soaking of coal tar, and the carbonaceous deposit from gas during its liberation from the coal. My experiments upon sugar, as a source of cementing carbon, showed me that at the best it would be expensive, and exceedingly slow in its action, from the low percentage of fixed carbon that it left. When the syrup used was composed of equal weights of sugar and water, the fixed carbon was only 13 per cent. of the liquid absorbed, or 26 per cent. of the sugar in the solution. At this rate, every ounce weight added to the carbons would cost 1½*d.* with sugar at its present cheap rate, besides the additional trouble of having the carbons to dry after each soaking. In using coal tar as a substitute, we first heated it to a temperature of 300°, so as to drive off the naphtha hydocarbons, which left it in a semi-pitched condition; and while still hot the coke bars were soaked in it till saturated, and sank to the bottom. The percentage of fixed carbon left in the coke after the soaking, and heated to redness, was 32·5 per cent. of the tar absorbed, or 2½ times the weight obtained from sugar, and secured at an infinitely less cost. Pure tar carbon is among the best that I have yet tried for Bunsen Batteries, and it was the success in some experiments that I was making with it that induced me to try it as a source of fixed carbon for the purpose now mentioned.

Three separate soakings in the tar, as described, and as many times heated to a high temperature, are necessary fully to close the pores of the coke. Before the last steeping, the carbons are ground upon a flat stone into the required shape. In grinding a little water is used, but only so much as may form the abraded powder from the carbons into a pasty state; and as the carbons are still absorbent at this stage, they imbibe the water from the paste, and leave the particles of carbon deposited in the pores on the surface, thereby leaving the close surface shown in the finished state. The carbons are again soaked in tar, and charred at a high temperature, when the process is completed by the final smoothing on a flat stone.

The manufacture of the carbons is conducted simultaneously with the process of gas-making; and thereby, with economy of heat, a considerable amount of carbon is deposited from the gas itself, in addition to the fixed carbon from the tar absorbed. For convenience of having them properly placed upon the coal in the retort, a long semicircular trough of iron is prepared (similar to a water run for eaves of houses) to contain from twelve to twenty at one time, and after the charge of coal is introduced, and before closed up, the long trough and its contents are thrust in over the coals, close up to the roof of the retort, and allowed to remain till the charge of coal is wrought off — a period of nearly three and a half hours. On being withdrawn, the carbons are scattered about, to cool as rapidly as possible, and prevent their burning away by the action of the air; and when cold they receive the slight rub to smooth them which finishes the process.

I do not wish it to be understood that I consider these carbon elements have reached their perfect state. This notice only shows the process in a comparatively infant stage; and I hope to be able to prosecute the experiments to greater maturity, so as to be able to place a still better article in the hands of the student of electricity.

PHARMACY, TOXICOLOGY, &c.

The Preparation of an Aërated Chalybeate Water, by M. Sarzeau.[1]

When clean pieces of iron are placed in a solution of carbonic acid prepared at 50° Fahr., and under normal pressure, small bubbles of gas are seen to form, which increase in size and are slowly disengaged. If platinum wire is rolled round the pieces of iron, the phenomenon is more apparent, and the experiment quicker made. By leaving the iron in the liquid until no more bubbles are seen to form, we obtain a liquor with a marked inky flavour, and which has all the properties of a solution of a protosalt of iron. If the liquor be heated it is at first turbid, then becomes milky, afterwards ochry, and at last, when it boils it suddenly changes to a deep brown. On cooling it deposits a substance of the same colour, which, separated by filtration, dried in the air, and dissolved in hydrochloric acid gives a mixture of the protochloride and perchloride of iron. If a magnet be brought in contact with the brown matter when dry it is found to adhere, showing that by heating a solution of carbonate of iron magnetic oxide is formed.

The preparation of an aërated chalybeate water is very simple. We have only to place some clean pieces of iron in the upper vessel of one of the ordinary gazogenes, set the apparatus in a cool place for 48 hours, by which time a liquid is obtained which only differs from the before-mentioned in the excess of carbonic acid which it contains. The taste is sensibly inky, but it is not at all disagreeable so drink.

Two experiments have been made to determine the amount of carbonate of iron in solution. In both cases a quantity of peroxide was found corresponding to rather more than half a grain of the protocarbonate in 100 grammes (3 ozs. 1½ drs. 13 grs.) of the water. The quantity of iron in the water may be increased or diminished by leaving the two in contact for longer or shorter periods.

On Tannate of Bismuth, by M. Cap.[2]

Tannate of bismuth has been introduced in France as a remedy for obstinate diarrhœa. It is prepared by first precipitating the oxide of bismuth from a solution of 44 parts of the crystallised nitrate by means of an excess of strong caustic soda. The precipitate is collected on a cloth and carefully washed. It is then triturated in a mortar with 20 parts of pure tannin. The magma is then diluted with water, the whole is thrown on a cloth, washed, and then dried either in the open air or in a slightly heated closet.

The salt has a yellowish appearance; it is insoluble and consequently almost tasteless; it is easily suspended in a mucilaginous vehicle, in syrup, or in glycerine; and and can also be administered in the form of pills, or of an electuary.

[1] *Journ. de Pharm. et Chimie*, 23 Jan. 1860.
[2] *Répertoire de Pharmacie*, t. xvi. p. 241.

Its composition when thoroughly dry represents:

Oxide of bismuth	53
Tannin	47
	100

The above mode of preparation is very simple and at the same time the most rational. Most of the insoluble tannates are obtained by double decomposition; but the salts of bismuth and especially the nitrate, are in great part decomposed by water, and to keep them in solution it is necessary to have a great excess of acid, which, in the present case, would prevent the precipitation of the tannate of bismuth. It is better then to effect the combination directly, by acting on one equivalent of oxide of bismuth with one equivalent of tannic acid. The tannic acid may be dissolved in alcohol, ether, or even water, and then the tannin obtained in a resiniform mass can be used, which is cheaper than that obtained in the usual form.

The tannate is administered in doses of 30 grains.

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

Friday, 3 *Feb.* 1860.

On the Mineral Treasures of the Andes, by Frederick Field, *Esq.*

I am very much afraid that after the lectures you have been in the habit of hearing at this Institution, the subject to-night will not prove very attractive. I have no experiments to show you, as the subject scarcely admits of experimental demonstration, and I think you will agree with me, that unless experiments serve to illustrate the truths advanced, they are of little value; when merely dragged in for the purpose of showing something pretty or amusing they are alike derogatory to the audience and the lecturer. May I claim your forbearance, then, this evening, I am lecturing here for the first time: I have been immediately preceded by two eminent philosophers, and I have only recently returned to England, after a long absence, from very distant lands. The great extent of country which lies between the Cordilleras on the east and the Pacific Ocean on the west is excessively rich in mineral productions, of which many are interesting not only as regards their commercial value, but also from their rarity and occasional novelty. It may be presumed that from the great extent of country, the difficulty of access in certain seasons of the year, as well as the comparatively few labourers in the field of science, that much still remains to be investigated. However, European enterprise and capital have done much in developing the resources of the country. The miner, finding a ready purchase in the smelter or merchant for the minerals he discovers, with an endurance scarcely conceivable, traverses mountain and valley, hill and plain, in search of new wealth, and when found, he makes his lonely habitation on some solitary summit where he remains often for months together, heedless alike of the silence or the storm. Of course in his travels he occasionally meets with minerals of which he has little cognizance, but from their metallic lustre, high specific gravity and other physical appearances, he deems them not wholly destitute of value. By exercising a little tact and discretion many new species can be thus obtained, for the miner, ever ready to know the marketable worth of the various ores he meets with, brings down for examination very curious minerals, especially to those who interest themselves in his labours.

In speaking to-night of the treasures of the Andes we shall confine ourselves particularly to the three metals and their compounds, which really constitute the chief wealth of that part of the world, viz. gold, silver, and copper. Copper,

at the first glance, may not appear so important as the two precious metals, yet in a commercial point of view it stands first on the list, many provinces in the northern part of Chile being mainly dependent for their support upon the various copper mines. There is an old adage in South America: "A gold mine must lose; a silver mine may lose; a copper mine must gain." This proverb does not always hold good, as many have been ruined in extracting copper, and many have made immense riches in searching for silver, but it simply implies that gold and silver are not generally found in such perfectly formed veins, or rather that the treasures in those veins occur in bunches, and then cease altogether for many yards, whilst copper generally continues throughout in more or less abundance.

We will divide the copper ores of the Andes into three classes:

1. Those destitute of sulphur, antimony, and arsenic.
2. Those containing sulphur, but free from antimony and arsenic.
3. Those containing sulphur, antimony, and arsenic, or the two latter without sulphur.

Native copper exists in considerable quantities, both in the higher ranges of the Cordillera and also comparatively near the coast. The province of *Andacollo* perhaps yields it in the largest quantity, and very often of considerable purity, although nearly all specimens contain traces of gold, antimony, arsenic, and silver. It occurs not only in large amorphous masses, but often beautifully crystallised in octahedra. It generally has a pure clear red colour, sometimes however whitish or of a brassy appearance. When this latter is the case it usually contains arsenic. *Red oxide of copper* is found associated with the native metal very often in large masses, but often in fine ruby crystals. Sometimes these crystals have a very dark colour, becoming almost black, but on crushing or filing, they afford the bright cochineal red powder so characteristic of the suboxide.

The black oxide was considered until quite recently a very rare mineral, occurring only ocasionally bordering the larger specimens of red oxide, but a discovery last August of a mine in the extreme north of Chile, has afforded splendid masses consisting essentially of the protoxide. This mineral has a very singular and novel appearance, resembling the fibrous variety of hornblende. Its analysis has not yet been published. Of the silicates of copper large quantities are found—the black, blue, and green. These ores, as may be supposed, are very hard to smelt, consisting entirely of silicic acid, oxide of copper, and water, but being perfectly free from antimony and arsenic, when well fluxed by the addition of suitable quantities of oxide of iron or lime, yield very pure copper. The black silicate is termed *metal aterciopelado* or velvet metal, from its deep black colour and soft feel and aspect. The silicates of copper are not found crystallised, but in masses more or less hard, according to the quantity of metal they contain; the harder the mineral the poorer it is in copper. The silicates often assume the botryoidal form; they are termed *llanca* by the Chilinos. A very interesting double silicate of manganese and copper occurs in Tambillos, and I have recognised the same mineral in other parts of South America. It is soluble in dilute hydrochloric acid, even in the cold, with evolution of chlorine, leaving a white residue of silicic acid. It is termed in Chile *metal de carbon*, from its striking resemblance to ordinary coal.[1]

The carbonates of copper are abundant, but no true malachite has yet been noticed, at least such as would bear comparison with that from Australia, Russia, or the west coast of Africa. It exists generally in amorphous and earthy masses, though sometimes finely crystallised in starry tufts of slender prisms. The blue carbonate is found occasionally very beautifully crystallised in the *Checo* mine, near Copiapo, but can hardly be considered an abundant mineral.

[1] The analysis of this mineral, as well as of others mentioned in the Lecture, are appended at the conclusion.

Phosphates of Copper.—Until lately the phosphates were unknown in the western part of South America, but have lately been discovered in the mineral district of Tambillos, consisting of 4 equivalents of oxide of copper, 1 of phosphoric acid, and 3 of water (*tagilite*); and 4 oxide of copper, 1 phosphoric acid, and 1 water (*liebethenite*). A very singular combination of phosphate of copper and lime, containing 2 atoms of phospho-calchite ($6CuO.PO_5.HO$) and 10 tribasic phosphate of lime, $10(3CaO.PO_5)$, with 1 chloride of calcium, occurs in fine bluish-green crystals, associated with apatite, in the same mine, from which the tagilite and liebethenite were derived.

Atacamite.—(Oxychloride of copper.)—This mineral is pretty extensively distributed through the northern parts of Chile, Bolivia, and Peru. Throughout all the district east of Copiapo it is found abundantly, and generally beautifully crystallised. It contains 1 atom of chloride, 3 oxide of copper, and 4 of water, although I have found 5 equivalents, and Berthier mentions a specimen from Cobija with 6 equivalents of water. A curious artificial formation of *atacamite* was observed in a large smelting establishment in Chile. The furnaces were connected with a large chimney by means of a horizontal canal or culvert running close to the seam. This culvert was built of brick, excepting the floor, which was simply the natural sand near the beach, and consequently impregnated with alkaline chlorides and sulphates. The finely-divived oxide of copper, resulting from previously calcined regulus, was blown by the draught from the furnaces into this chimney, and lodged on the floor. In the course of time layer after layer of dust was formed, so that the lower ones were protected from the flame, yet still were kept warm by the heat from above. The strata next the sand combined with some of its saline ingredients, and became converted into sulphate and oxychloride of copper, together with *brochantite* or subsulphate. Between 3 and 4 tons were formed in this manner.

Vanadiate of Copper, in association with vanadiate of lead, has been found in the Mina Grande in masses of considerable size. Rough analysis yields from 13 to 16 per cent. of vanadic acid.

In the second division of copper ores we have those which contain sulphur, or sulphur and iron. The disulphide or *copper glance*, Cu_2S, occurs often in a state of great purity, sometimes containing 79·4—79·6 of copper, with mere traces of iron. The protosulphide or indigo copper is generally intimately mingled with sulphate of lime. By powdering the mineral and digesting in cold water the sulphate is removed, and the residue is nearly pure protosulphide. The double sulphides of copper and iron are perhaps the most important ores in Chile, at least the greatest part of the copper derived from the Andes is extracted from this class of mineral. In the hill of Tamaya there exists an immense vein of the blue double sulphide, the purer specimens containing about 56 per cent. copper. Perhaps this mine (the *Pique*) is, not even excepting the celebrated Burra-Burra, the most prolific in the world. It belongs to one individual, and the fortunate owner, as may be supposed, derives an immense income from the sale of the ores. And it may be well here to speak of the Chile miner, a portrait of whom I have here dressed in his ordinary mining habiliments. He is capable of undergoing an immense amount of fatigue. The ascent and descent of mines, where there are few or no appliances of machinery, is never an easy task, but when burdened with two or three hundred weight of stone or metal it is peculiarly trying. And yet the miner, day after day, goes on with his employment, digging away at his work and carrying up the rock to the surface. In the year 1851 I begged Señor Urmeneta, the proprietor of some of the richest mines in Chile, to send me some specimens for the Great Exhibition, as samples of Chile mineral wealth. He immediately forwarded two large stones, one weighing 356 lbs. and the other 349 lbs., and he told me that perhaps the strength of the miner who excavated these masses and brought them from the mine was as striking as the richness

of the specimens themselves. Both stones had been taken from a depth of more than 300 feet, and had separately been borne on the shoulders of a man, he having to ascend, not by ladders or other aid, but by climbing up the nearly perpendicular slope of the mine. And the food the miner principally lives upon is an interesting subject for physiologists. He seldom takes meat, and when he has that luxury it is simply served out in long thin strips, which have been dried in the sun. His chief diet is the haricot bean, and without this nutritious vegetable he could never get through the work required of him. The beans are boiled until they are quite soft, and eaten with a little bread.

Guayacanite.—This mineral was obtained from a mine many thousand feet above the level of the sea, and consists entirely of sulphur, arsenic, and copper. I named it from the large smelting works of Guayacan, rather prematurely perhaps, as a mineral very similar had been previously discovered in Peru, and called *enargite*. The great distance I was from scientific friends, and the interrupted communication of books and periodicals, rendered it difficult for me, at most times, to know what was doing in other parts of the world. The mineral is interesting, as a *pentasulphide* of arsenic is in union with the disulphide of copper ($3Cu_2S + AsS_5$).

Domeykite, named in honour of M. Domeyko, professor of chemistry and mineralogy in the university of Santiago, contains 6 equivalents of copper to 1 of arsenic. Many years ago Mr. Faraday analysed a somewhat similar mineral, and the analyses were confirmed by Dr. Blyth in 1848. The substance these chemists investigated contained a certain portion of arsenious acid, whilst *Domeykite* is a simple union of the two metals.

Algodonite is another compound of copper and arsenic, named after the mine *Algodones*, from which it was obtained, It consists of 12 of copper and 1 of arsenic ($Cu_{12}As$).

I forgot to mention when speaking of the compounds of sulphur with copper, the two minerals *cyanose* and *brochantite* one the ordinary sulphate, the other a basic salt containing 4 atoms of oxide of copper to 1 of sulphuric acid.

Before referring to the silver minerals allow me to dwell for one moment upon this beautiful substance which we have before us, the bisulphate of sesquioxide of iron. It occurs in the mine near Copiapo in large nodules, each nodule being composed of numerous beautiful gold coloured fibres, radiating from a centre. It consists of $Fe_2O_3.2SO_3 + 10HO$, and is speedily decomposed by boiling water.

For a long time the chief place of export for the silver from Chile was the port of Coquimbo, a view of which is before you, but some five and twenty years ago an immense discovery of the precious metal was made in a very curious manner. A wood-cutter named Juan Godoy was benighted upon the hill of Chañarcillo, about forty miles from the city of Copiapo, and determined to rest there till morning. Having unsaddled his mule he kindled a small fire and lay down to rest. At early dawn he re-saddled his mule, and was upon the point of starting when he moved away with his foot the ashes left by the burning wood, in search of some embers, by which to light his cigarito. Immediately under the ashes he observed a shining metallic surface, and by means of his knife or other rude implement, he managed to extract a large lump of ore. Ignorant of its value, he brought it to Copiapo and showed it to a watchmaker, who told him it was lead, and offered him a dollar for the lump, at the same time telling him he would give him a similar sum for every piece of metal he might bring of the same kind as that which was now before him. Juan Godoy went backwards and forwards after this many times bringing lumps of the mineral to the artisan. He was watched, however, and soon the secret was discovered. He had hit upon a rich vein of silver, every piece he had excavated being nearly solid metal, which the watchmaker knew perfectly well. What was the sequel of Godoy's history I do not know. I believe he did not die in affluent circumstances, but he has had honours paid to his memory. A town has sprung up at the foot of the hill, where he, benighted, first found the ore which has since made others so wealthy, and is called after his mame, and his statue is erected in the chief square of the city of Copiapo. Since then more than ten millions sterling have been extracted, and what is very remarkable, although subsequent research has discovered numerous rich silver veins in the same hill, which is so pierced and honey-combed as almost to resemble a gigantic rabbit warren, no mine has equalled the one first discovered. Godoy kindled his fire upon the very richest vein in the whole hill, and from that time to the present day it has proved amongst its glittering neighbours to be the wealthiest and the best. Many interesting varieties of silver and its compounds have been found in Chañarcillo —the chloride, chloro-bromide, iodide, and bromide; the sulphide, light and dark *rosicler*, *polybasite*, &c. The native silver itself when associated with the chloride or chloro-bromide is nearly chemically pure; when found with the *rosicleres* it always contains arsenic or antimony.

It may be supposed that the immense treasures obtained in this province, raised the city of Copiapo to a state of considerable importance. The port from which the specie and ores were shipped was found to be altogether too exposed and inconvenient, and another one was opened more to the north, now the thriving *port of Caldera*. A railway was formed from thence to Copiapo, subsequently an extension line was projected to Pavillon, some twenty-two miles further east, and now there is a railway as far as Chañarcillo. What used to be only a very few years ago a long and troublesome journey is now accomplished in a few hours.

The silver mines in *Arqueros*, a few leagues from Coquimbo, yield the native amalgam *Arquerite* (Ag_6Hg). Domeyko has discovered no less than five different amalgams in Chile and Bolivia.

Mercury exists in considerable quantity, chiefly as cinnabar (HgS). *Mercurial fahlerz* is found in some mines, and the very rare mineral *ammiolite*, derived doubtless from the oxidation of the former. I obtained fine specimens from a mine near Andacollo, researches upon which have appeared in the *Journal of the Chemical Society*.

In conclusion, I have to thank you for your kind attention to what can necessarily have only been a rapid and most imperfect sketch of some of the mineral treasures of the Andes.

SOCIETY OF ARTS, *Wednesday*, 15 *Feb.* 1860.

Figure Weaving by Electricity formed the subject of the paper read at this meeting of the Society of Arts, by the Secretary Mr. P. Le Neve Foster, who gave a most lucid and interesting description of the Jacquard loom, with the subsequent improvements of Riding, Barlow, Laforest and others, which however our limited space will not allow us to transcribe, so we will turn at once to the description of *M. Bonelli's Electric Loom*, the object of which is to supersede the present costly and complicated system of perforated cards, by an electro-magnetic arrangement of a highly ingenious character.

But Mr. Foster must now speak for himself: —

"In the first place it must be understood that the special object of M. Bonelli's machine is to do away with the necessity for the Jacquard cards used to produce the pattern at the present time, the source of delay and very considerable cost, more especially in patterns of any extent and variety of treatment. M. Bonelli uses an endless band of paper, of suitable width, the surface of which is covered with tinfoil. On this metallised surface the required pattern is drawn or rather painted with a brush in black varnish, rendering the parts thus covered non-conducting to a current of electricity. This band of paper bearing the pattern, being caused to pass under a series of thin metal teeth, each of which is in connection with a small electro-magnet, it will readily be conceived that as the band passes under these teeth, a current of electricity from a galvanic battery may be made to pass through such of the teeth as rest on the metallised or conducting portion of the band, and from such teeth through the respective coils surrounding small bars of soft iron, thus rendering them temporary magnets, whilst no current passes through those connected with the teeth resting on the varnished portions. Thus, at every shift of the band, each electro-magnet in connection with the teeth becomes active or remains inactive according to the varying portion of the pattern which happens to be in contact with the teeth. In a moveable frame opposite the ends of the electro-magnets, which, it should be stated, lie in a horizontal direction, are a series of small rods or pistons, as M. Bonelli terms them, the ends of which are respectively opposite to the ends of the electro-magnets. These pistons are capable of sliding horizontally in the frame passing through a plate attached to the front of it. When this frame is moved so that the ends of the pistons are brought into contact with the ends of the electro-magnets they are seized by such of them as are in an active state, and on moving the frame forward, those are retained while the others are carried back with it, and by means of a simple mechanical arrangement become fixed in their places; thus there is in front of the frame a plate, with holes, which are only open where the pistons have been withdrawn, and this plate, as will be readily understood, acts the part of the Jacquard card, and is suitable for receiving the steel needles which govern the hooks of the Jacquard in connection with the warp threads as ordinarily used.

Each shift of the pattern, combined with the backward and forward movements of the frame bearing the pistons, produces a different series of holes in the plate, which thus becomes what may be termed a universal Jacquard card, changing its face each contact, in accordance with the requirements of the pattern. Thus the electric loom gets rid of all those costly preliminaries which are required for the preparation of the cards, accomplishing instantaneously and automatically an analogous operation." When a pattern containing several colours is to be produced, "the design is prepared on the metallised paper, so that the coloured parts are represented by the metallised portion of the band, but each separate colour is, by removing a very thin strip of the foil at the margin, insulated from its neighbouring colour. Then all the pieces of foil thus insulated, which represent one colour or shade, are connected with each other by means of small strips of tinfoil, which pierce through the paper and are fastened at the back, and are conducted to a strip of tinfoil which runs along the edge of the band, there being as many such strips of tinfoil as there are colours. Thus each special colour of the pattern, in all its parts, is connected by a conductor with its own separate strip of tinfoil, and by bringing the wire from the pole of the battery successively into contact with the several strips, a current of electricity may be made to pass in succession through the several parts of the design on the band representing the separate colours of the design. Thus, assuming four colours, 1, 2, 3, 4, there would be four strips of tinfoil running the length of the band, insulated from each other, each of which would be in connection with its own separate colour only. At any given moment, the thin plates of metal resting on the pattern would touch it in a line which, as it passes over the width of the pattern, would run through all, or any one or more of the colours, but the electric current would pass only through those plates which rest on the one colour, represented by the strip with which the pole of the battery at that instant happened to be in contact."

We are forced to omit various interesting details relating to the electrical contrivances of this invention, but must pass on to the question of comparative expense, a not unimportant inquiry in a commercial point of view; here we are told that: —

"The electric power required for the loom is small, and that derived from two cells of a Bunsen's battery of ordinary dimensions is sufficient. The cost of this per day is calculated at not more than one penny.

It is thus that M. Bonelli gets rid of the cards, which we have seen are not only a source of expense, but of considerable delay as well, and by this system the operations are reduced to tracing the design on the metallised paper with a non-conducting varnish. The rest of the operations remain the same. The thin plates passing over, the pattern becomes as it were alive under the action of the electric fluid, feeling out the design and instantaneously and unerringly improvising for the moment the card required for the production of the design on the fabric.

The inventor claims the following as the results of his invention: —

1. The great facility with which in a very short time, and with precision, reductions of the pattern may be obtained on the fabric by means of the varying velocity with which the pattern may be passed under the teeth.

2. That without changing the mounting of the loom or the pattern, fabrics thinner or thicker can be produced by changing the number of the weft, and making a corresponding change in the movement of the pattern.

3. The loom and its mounting remaining unchanged, the design may be changed in a few minutes by the substitution of another metallised paper having a different pattern.

4. The power of getting rid of any part of the design if required and of modifying the pattern.

The length of paper required for a pattern depends, of course, on the nature and extent of it, but an idea may be formed generally by recollecting that at each stroke of the shuttle a card of the Jacquard apparatus is brought into operation, while in M. Bonelli's invention, the paper having the pattern moves at the rate of a fraction of a millimetre at each stroke. M. Bonelli gives the following calculations by way of comparison between the old and the new systems.

He takes a damask design on the old system, requiring 4000 cards, and with 400 Jacquard wires.

The cards will cost, at 12*s.* per hundred, 24*l.* The time employed for the *mise en carte* of the pattern, the reading it off, and punching 4000 cards, cannot be taken at less than about five weeks.

On the electric system, the executing the design on the metallised paper, ready for putting on the loom, he calculates at 6*l.* The time employed would be a week, showing a difference in favour of M. Bonelli's system, in this case, of 18*l.* in money, or 75 per cent. and in time of 80 per cent."

It is further stated that the electrical apparatus can be applied to any of the existing looms for about 20*l.*, an amount which seems quite insignificant when the cost of a single set of Jacquard cards is considered. At the conclusion of the paper an animated discussion took place, but being chiefly of a technical character, need not be reported in these columns. The new loom, together with many specimens of its powers, and several models and diagrams were exhibited. The thanks of the Society were unanimously voted both to Mr. Foster and the eminent and ingenious Sardinian.

CHEMICAL SOCIETY, 16 *Feb.* 1860.

PROFESSOR BRODIE, *F.R.S. President, the Chair.*

DR. GUTHRIE read a paper *On some Derivatives from the Olefines.* After referring to the bodies he had previously described, namely, $C_4H_4Cl_2S_2$, and $C_{10}H_{10}Cl_2S_2$, and $C_{10}H_{10}ClS_2$, he pointed out the mode of producing a new body, which he termed the bisulpho-chloride of chlorethylen. Dry pure ethylen was passed through boiling bisulphide of chlorine contained in a retort attached to a condenser, directed upwards so as to cause the flowing back of the distillate. The liquid was then heated in a smaller retort until the temperature rose to 180° C. The residue in the retort was washed first with water, then with dilute caustic soda, and afterwards purified by means of ether. Its composition was found to be $C_4H_2S_2Cl_2$, and its formation was described by the equation $C_4H_4 + 3S_2Cl = C_4H_3S_2Cl_2 + HCl + S_4$. Bisulpho-chloride of chlorethylen is a transparent liquid of light yellow colour, of a sweet pungent taste, and of a pepperment-like odour. It is soluble in ether and alcohol, insoluble in water. It is not volatile without decomposition. Its sp. gr. is 1·599. Dry chlorine gas was passed through bisulpho-chloride of chlorethylen until the heat first developed had abated, and subsequently for two hours at the temperature of 100° C. The product after purification was found to have the composition $C_4H_2Cl_2SCl$, and was denominated the chlorosulphide of bichlorethylen. It is a faintly yellowish transparent liquid, of a persistent suffocating smell, miscible with ether and alcohol, but not with water. It may be volatilised in a current of dry carbonic acid. Its sp. gr. is 1·225. Identically the same compound was obtained by passing chlorine through bisulphide of ethyl. The bisulpho-chloride of amylen $C_{10}H_{10}S_2Cl$, described in a former paper, was also subjected to the action of chlorine, and a product obtained whose analysis corresponded with the formula $C_{10}H_7Cl_3SCl$ chlorosulphide of terchloramylen. It is a transparent, non-volatile, pale yellow liquid of sp. gr. 1·406, and greatly resembling in its general properties the body last described. Dr. Guthrie also subjected amylen to the action of nitric acid. A current of air, charged with the vapour of amylen was passed through boiling strong nitric acid, whereby a fatty crystalline sublimate was condensed in the receiver. This after purification, and crystallisation from boiling ether, occurred in long rectangular prisms. By analysis it proved to be binitro-amylen $C_{10}H_8(NO_4)_2$. This body furnishes the first instance of a nitro-substitution product of an olefine. It is insoluble in cold and boiling water, nearly insoluble in cold but readily soluble in hot alcohol, soluble in ether and bisulphide of carbon. Heated by itself in a test tube, it is decomposed with explosive violence. Heated in the air it burns with a livid flame.

DR. ODLING pointed out the relations of Dr. Guthrie's products to the mercaptan series of compounds, thus:

$C_{10}H_{10}Cl_2S_2$ and $C_4H_4Cl_2S_2$ analogous to $C_4H_6S_2$ mercaptan.
$C_{10}H_7Cl_3S$ and $C_4H_2Cl_3S$ analogous to C_4H_5S sulphide of ethyl.
$C_{10}H_{10}ClS_2$ and $C_4H_3ClS_2$ analogous to $C_4H_5S_2$ bisulphide of ethyl.

DR. ODLING made a verbal communication *On the direct oxidation of chlorhydric acid.* When air charged with the vapour of chlorohydric acid was passed through a solution of permanganate of potassium acidulated with sulphuric acid and heated in a water bath, a liquid distillate was obtained free from any smell of chlorine but having the characteristic sweet smell of hypochlorous acid, $HCl\Theta$. It had a feeble acid reaction, and possessed bleaching properties which did not disappear upon keeping the liquid for an hour at the temperature of 100° C. After evaporation to a small bulk, and neutralisation with caustic potash, it yielded crystals of chlorate of potassium. The author represented the acids of chlorine as follows, and considered the oxygen acids as oxydised compounds of chlorohydric acid.

HCl	Chlorhydric	Acid.
$HCl\Theta$	Hypochlorous	,,
$HCl\Theta_2$	Chlorous	,,
$HCl\Theta_3$	Chloric	,,
$HCl\Theta_4$	Perchloric	,,

CORRESPONDENCE.

Chemical Nomenclature.

To the Editor of the CHEMICAL NEWS.

SIR, — In glancing over some of the recent numbers of the CHEMICAL NEWS, I observed a passage of yours in reply to a correspondent, *A. P. S.* in No. 6, p. 72, which I think requires further elucidation at your hands. You say that being "better acquainted with the recent literature of chemistry, he (*A. P. S.*) would find no difficulty in the terms nitrate of *potassium*, chlorate of *barium*, &c. to which he alludes." I can say that all the manuals that have come to my hands — Kane, Brande, Graham, Miller, Gregory, &c. give no explanations that would lead any student to infer that the names above referred to, indicated the compound, $KNO_6 = KO.NO_5$ or $BaClO_6 = BaO.ClO_5$. They do explain, and advocate the propriety of attributing to the hydrogen of such acids as hydrochloric, sulphuric, nitric, phosphoric, and other similarly constituted acids the power of acidification rather than to the other components; also the consistency of having not *two* classes of acids and *two* classes of salts — such for instance as the hydracid and oxacid salts — but one class of acids, and one of salts, the nomenclature of which should not exhibit such inconsistent diversity as the system of nomination and representation of the preceding classes as hitherto practised manifest.

If in the new system of formulæ tabulation you assume for the positive element, hydrogen in the acid $HO.NO_5$ or HNO_6 — nitric acid — the acidifying power, and make the other elements, NO_6, a compound radical, serving merely to give a distinctive character to the assumed functions of the H, I think you should adopt some other term to express the compound, $H.NO_6$, besides the hackneyed name *nitric acid*; and this is also the case when a salt of such an acid is spoken of. Besides, the manuals state that, as a rule, *simple* bodies combine with such, and copulated bodies with others similarly constituted in forming compounds, excepting

where a copulated or compound body exhibits properties entirely analogous to the simple substance or element. Now if you do not adopt a name for the nitric acid, as represented in the preceding instance, expressive of the fact that the NO_5 has functions in the salt KNO_6 analogous to those of Cl in the compound KCl, I think it is too much to expect that students who may not be very far advanced in the science will comprehend what sort of a compound is meant, when you retain the old name for the acid — thus giving the idea that the anhydrous or combining radical NO_5 is indicated — and combine it with a salt-base or metal potassium K, calling the resulting compound by the incongruous name — *nitrate* of *potassium*. I think you would be doing a great service to chemistry if you advocated a consistency in the symbolic representation of chemical bodies and in their titles. If, for instance, the compound $KO.NO_5$ or KNO_6 were called instead of *nitrate* of *potassa* or *nitrate* of *potassium*

	Nitratide of potassium
KSO_4 (sulphate of potassa)	Sulphatide of „
K_3PO_8 (phosphate of potassa)	Phosphatide of „

and so on through all the higher oxygen compounds of acid and base, I think it would be much simpler, and the names would not be unnecessarily or inconveniently lengthened, at the same time that a unique analogy of the title and composition of all the salts would be secured.

In the same way the compound $KO.NO_3$, or KNO_4 instead of *nitrite* of *potassa* or *nitrite* of *potassium*, could be named

	Nitronide or Nitritide of potassium
KSO_3 (sulphite of potassa)	Sulphitide of „
K_2PO_6 (phosphite of potassa)	Phosphitide of „

Certainly every experienced chemist would not fail to comprehend what substances were referred to in the paragraph in No. 3, p. 36 of your journal, to which doubtless your correspondent *A. P. S.* alluded, but the propriety or expressiveness of the names given to those compounds in said paragraph, deserve, in my opinion, no thanks for it.

Hoping to see you using your influence with your numerous patrons to place this and similar questions on a more consistent and unalterable foundation; and wishing you every success in your career, — I am, &c.

YOUR WEEKLY GUEST.

The Cavendish Society.

To the Editor of the CHEMICAL NEWS.

SIR,—The annual meeting of the Cavendish Society is to take place as usual on the 1st of March. What is transacted at these meetings we only know by the short reports issued by the council. Whether any subscriber ever attends to complain of the slowness with which the Society's books are published, and of the way the council have of making promises and never keeping them, I do not know. I do not attend the meetings myself, but I am anxious before the next takes place to call the attention of the subscribers to one or two facts.

The society was started in 1848, and in their first report the council proposed a list of books which they thought it would be desirable to publish. Among them was Persoz' *Art and Theory of Calico Printing*; Essays by Saussure and others on *Vegetable Chemistry*; Rammelsberg's *Dictionary of the Chemical part of Mineralogy*; Kopp's *History of Chemistry*; Otto's *Economic Chemistry*. Afterwards were announced a volume of *Chemical Essays* on many subjects; Plattner on the *Roasting of Ores*; and last, but not least, Rose's *Analytical Chemistry*. Of these works not one has been issued, although two of them—the Essays by Saussure and Rose's work—have been announced as in progress. In the course of the eleven years, however, twenty-two volumes have been published, which at the rate of 10*s*. 6*d*. each to the subscribers cannot be considered cheap, especially for some four or five of them. It is true that the great value of Gmelin's work will compensate for much, but I do not see why the Cavendish Society should degenerate into a society for the publication of *Gmelin's Chemistry*. If the council do not intend to publish anything else, why do they not tell the subscribers so, finish the book at once, and let the Society die? The old Sydenham Society, which expired some time ago, has been reanimated with considerable success. If the Cavendish underwent the same process perhaps something better might be done for chemical literature.—I am, &c.

A SUBSCRIBER TO THE CAVENDISH SOCIETY.

Manchester, 22 Feb. 1860.

The Atomic Theory.

To the Editor of the CHEMICAL NEWS.

SIR, — In the number of the CHEMICAL NEWS for February 4th, 1860, I observed an argument for the atomic theory; based on the circumstance that the attraction between spheres which touch one another varies as their radii. From this it was argued, that indivisible atoms must exist; for if not, we might divide matter, until we should have portions whose radii = 0; and therefore there would be no attraction.

But, if this law of attraction be true, it must likewise be true for any size of sphere, and therefore for a sphere infinitely small. We could never divide matter to such an extent that the portions would have *no* diameter. The question of attraction is mathematical; and is distinct from any theories of the nature of matter.

Besides the objections that I put forward a short time ago, under the name of (GIMEL) a few others might be mentioned. For instance: the atomic theory does not assign any *properties* to the atom itself. It can have no *colour*, for colour relates to a number of atoms, influenced by a vibratory motion. It (*i. e.* the atom) cannot be spoken of as transparent or opaque. Transparency is a question of an undulation in or rather pervading the space between the particles of a body. It cannot be hard or soft. These properties depend on the amount of motion that can take place among the particles. It can have no weight; for the attraction is supposed to exist exterior to the atom. The only property it can have is size. It is difficult to imagine anything to have size and nothing else; size in the abstract can scarcely exist. So that we are almost obliged to admit that the atom cannot exist. — I am, &c.

A. REYNOLDS.

The Patent Medicine License.

To the Editor of the CHEMICAL NEWS.

SIR, — While the Budget is under consideration, I should be glad if you would call attention to the unfairness of the present charges for the license to sell patent medicines. We London druggists pay 2*l*. for this license; in other cities and boroughs they pay 10*s*. and in other places 5*s*. Now it is just where the license is charged least, that the most patent medicines are sold. In London (except at a few large houses in that special line who might be made to pay more) very few are sold. And yet we are made to pay eight times the sum for a license that a man pays who makes a good profit on the sale. I would suggest that the duty should at least be equalised, or that the larger sum should be charged where the most profit is made. In London there are only about 1000 druggists, not half of whom I believe take out the license. In the country there are about 20,000, who almost all take a license, and a good number of grocers besides.

I do not wish to see the country druggists charged the higher sum, although in fairness I think they ought to be; but I do contend that the London druggist (except the wholesale and special houses) should only be made to pay the lower.—I am, &c.

A LONDON DRUGGIST.

To the Editor of the CHEMICAL NEWS.

SIR,—In your number of the CHEMICAL NEWS of last week, in your report of a meeting held at Hanover-Square Rooms, I am represented as having said, "Bread food he considered especially bad—opium was as innocent, and less troublesome." What I intended to say was, "that aluminised bread food was as sure a poison as opium, or any other poison if long persisted in," and shall be obliged to you to make this correction in your next.—I am, &c.

C. H. J. ROUTH.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

Action of Soluble upon Insoluble Salts; Special Affinity of Phosphoric Acid for the Sesquioxides.—M. Guinet[1] shows that an insoluble phosphate of protoxide is completely decomposed by a soluble salt with a sesquioxide base, either cold or by boiling: the phosphate of the sesquioxide is precipitated.

Phosphate of Cobalt and Potash Alum.—The reaction is completed by boiling in less than an hour: the phosphate of cobalt, which is of a violet-red colour, is decomposed to form the colourless phosphate of alumina which is precipitated.

Phosphate of Cobalt and Chrome Alum.—The green solution becomes rose coloured after boiling for a few moments, and phosphate of chrominm is formed.

Phosphate of Cobalt and Iron Alum.—The decomposition is completely effected in a few minutes in the cold.

Other salts of the sesquioxide may be taken as well as the alums, and the author has verified the experiment with very different salts: the nitrate of iron, the tartrate of iron and potash, &c.

The phosphates of nickel and silver behave in the same way as the phosphate of cobalt, as does the phosphate of copper; but with the last the double decomposition takes place very slowly.

II. ORGANIC CHEMISTRY.

Crystallised Guaiacum Resin.—Prof. Hlasiwetz[2] has, after a long trial, found a way to change the greater part of guaiacum resin into crystals. He dissolves a pound of the resin in as much alcohol as will make a solution of the consistence of a thin syrup. This he strains through fine linen, and adds gradually, while still warm, half a pound of caustic potash in spirit, shaking them together. The whole is allowed to stand in a bottle about 24 hours. The magma obtained is then transferred to a strong linen cloth, and the fluid part carefully pressed out. The moist cake is washed with strong alcohol until the the alcohol runs away but slightly coloured. The mass is again pressed, then triturated with a small quantity of water, and afterwards heated in a dish until reduced to an uniform consistence. It is then transferred to a filter and washed with cold water until the salt is white, and the water runs away colourless. This potash salt (which is but slightly soluble in alcohol and water) may be obtained crystalline by dissolving it in a large quantity of dilute alcohol at the boiling point. From such a solution, as it cools, crystalline flakes separate. By cooling it very slowly larger crystals may be procured, which when dried have a pearly lustre. A second crystallisation gives them of a dazzling whiteness. From a solution of this salt in hot potash water, hydrochloric acid separates the resin. Immediately after the decomposition the resin is fawn coloured, soft, and sticky; it is washed with water, dissolved in alcohol, and the solution is allowed to evaporate spontaneously. By degrees it crystallises completely. The crystals appear scaly, or are aggregated together, have a pearly lustre, and a slight but most agreeable smell like vanilla.

They dissolve in ether, warm acetic acid, and dilute potash ley, but are insoluble even in warm ammonia water. Sulphuric acid dissolves them, acquiring a purple colour. The alcoholic solution gives with perchloride of iron an intense, beautiful green colour. Chloride of acetyl gives a substitution product, which may be obtained from an alcoholic solution in granular crystals.

It should be remarked that with this ingredient the blue reaction of tincture of guaiacum with oxidisable substances is not obtained.

From a mixture of the solution of the crystallised resin with a spirituous solution of soda a soda salt is precipitated, which may be purified like the potash salt.

Reactions of the Tincture of Guaiacum.—M. H. Schiff[3] observes that when iodine is added to the tincture of guaiacum, no coloration, or at most a dirty green colour, is seen. It is only on the addition of water that the liquid turns blue. Neutral salts do not interfere with this result; but a drop of acid is sufficient to hinder it. The blue colour produced by perchloride of iron is changed to violet by hyposulphite of soda, but this colour soon disappears, leaving a colourless liquid. The solution obtained by digesting zinc with sulphurous acid also decolorises the tincture blued by perchloride of iron.

The tincture may be employed to discover the presence of nitric in sulphuric acid. It is only necessary to heat the suspected acid in a tube with a few iron filings, and to pass the gas disengaged into the tincture of guaiacum, which is immediately turned blue if the gas contain any hyponitric acid. The resin of guaiacum dissolves in concentrated sulphuric acid, colouring it red; water causes a violet precipitate from the solution.

Mixtures of Ether with Water and Alcohol.—M. H. Schiff[4] shows that a saturated aqueous solution of ether at 54° F. has a density of 0·983.

Alcoholic solutions of ether gave him the following results:—

Alcohol.	Density.
0 per cent.	0·729
10 „	0·737
30 „	0·756
40 „	0·765
60 „	0·779
70 „	0·786
90 „	0·801
100 „	0·809

These values correspond with the formula

$$D = 0{\cdot}729 + 0{\cdot}000966\,p - 0{\cdot}00000222\,p_2,$$

in which p represents the weight of the alcohol.

III. CHEMICAL ANALYSIS.

Estimation of Titanic Acid in Silicates.—Scheerer[5] remarks that very many silicates contain small quantities of titanic acid, which hitherto has been overlooked. When a silicate is decomposed in the ordinary way, by acids or carbonate of soda, the greater part of the titanic acid is found in the precipitate obtained by adding ammonia to the solution filtered from the silicic acid; but some remains with the silicic acid. To separate this, the latter is treated with fluoric and sulphuric acids, and the residuum is added to the precipitate, which has been previously ignited. The united mass, in which, besides titanic acid, alumina, oxide of iron, manganese, and some lime and magnesia may be present, is fused with bisulphate of potash, the temperature being gradually raised until the greater part of the sulphuric acid in excess is dissipated. The fused mass is then dissolved in a large quantity of water, and sulphuretted hydrogen is passed through until the peroxide of iron is reduced to protoxide. After this the solution is boiled, and the fluid being kept hot, carbonic acid is passed through.

[3] *Ibid.* Bd. cxi. s. 372.
[4] *Ibid.* s. 373.
[5] *Ibid.* Bd. cxii. s. 178.

The bases remain in solution while the titanic acid is precipitated.

Detection of Fusel Oil in Spirit of Wine.—Chloride of calcium in small pieces is put into a beaker, and just enough of the suspected spirit is poured over to moisten the whole; the beaker is then covered with a glass plate and allowed to stand. In a short time, if fusel oil be present, the smell will be distinctly perceptible, and will become stronger and stronger on standing for some hours. In this way the least trace of fusel oil can be recognised; but when the quantity present is very small, the mixture must be left together longer before the experimenter smells it, and then the nose must be applied frequently at short intervals.

The impossibility of recognising small quantities of fusel oil in spirit depends upon the insensibility of the olfactory nerves produced by the vapour of alcohol. If we wish to smell fusel oil alone we must prevent alcohol vapour from rising; this is best done by mixing the alcohol with chloride of calcium, which fixes it. Fusel oil also combines with chloride of calcium, but the combination is not odourless, while the alcohol is held so fast that it does not disturb the smell of the fusel oil.[6]

IV. TECHNICAL CHEMISTRY.

Application of Mineral Oil for the Lubrication of Watches, &c.—The finest animal and vegetable oils are found after some time to act on and oxidise the metals; Dr. Artus[7] has therefore tried to find a substitute for them free from the above objection. Mineral oil purified in the following manner he has found to answer the purpose well. First of all the oil is to be shaken with saturated chlorinated soda, and allowed to stand. The supernatant oil is then poured off and shaken repeatedly with milk of lime and allowed to become clear. The oil is again separated and then mixed with one third of its volume of a strong solution of soda and subjected to rectification. Many trials of this have been made by mechanicians, who speak strongly in favour of it.

Purification of Paraffin.—Those paraffins which do not become clear, and remain too soft after purification with sulphuric acid, P. Wagenman[8] of Neuwied recommends to be melted with a small percentage of oleine, then to be pressed while warm, and afterwards boiled with a weak alkaline ley. He treats it with 5 or 10 per cent. of oleine, and as this does not dissolve paraffin, the mineral oil and the oleine only are removed by pressure. The mixture of mineral oils and oleine is distilled with superheated steam. The mineral oils distil at 220°, and oleine at 280°.

LABORATORY MEMORANDA.

Lime-determinations.—To avoid the inaccuracy and loss of time nearly always resulting from the ordinary method of determining lime, viz. by strongly heating the precipitate of oxalate of calcium, and converting the same into carbonate by repeatedly moistening with solution of carbonate of ammonium, I am in the habit of weighing the precipitate as *sulphate* instead. The addition of sulphuric acid or even of sulphate of ammonium *alone*, to caustic lime is hardly a safe operation, in an analytical point of view, if the mass in the crucible is at all bulky, but the solution I am about to recommend may be employed without inconvenience for the purpose indicated above. Three parts of pure *liquor ammoniæ*, of the ordinary strength should be just neutralised with pure sulphuric acid (previously diluted with its bulk of water), and the two parts of the ammonia-solution added. In each ounce of the fluid thus obtained 10 grains of chloride of ammoniun must be dissolved; the whole may then be filtered into a small reagent-bottle and appropriately labelled. It must of course entirely volatilise when heated on platinum foil. In this manner the lime is weighed as *sulphate* which may be strongly ignited without change, *one weighing* therefore being sufficient.—*Wentworth L. Scott.*

[6] *Polytech. Centralblatt*, 1859, s. 1627.
[7] *Ibid.* s. 75. [8] *Ibid.* s. 75, 76.

Estimation of Mixtures of Acids or Alkalies in Solution. — In the Chemical News, No. 9, p. 108, under the head "Laboratory Memoranda," there is a method proposed for analysing a mixture of acids or alkalies by saturation with two or more alkalies or acids; as I am unable to see that there is a any advantage or reason in the process, I send an equation which will really give the required result, if there is nothing else present besides the mixed acids or alkalies, or the quantity of other impurities is known. Let X and Y be the quantities of the two substances present in a known weight of mixture, then:

$$X = \text{Eq. of X} \left\{ \frac{\text{Wt. of mixed acids or alkalies} - \text{Eq. of Y} \frac{\text{Quant. acid or alkali saturated}}{\text{Eq. acid or alkali}}}{\text{Eq. of X} - \text{Eq. of Y}} \right.$$

The equivalents must in each case be taken which correspond to 1 Eq. of NaO, or 1 Eq. of $HO.SO_3$: thus, sulphuric acid = 49, tartaric acid $\frac{150}{2}$, and citric acid $\frac{192}{3}$.

Under the head "Correspondence," in the same Number, there is a supposed proof of the non-existence of indivisible atoms, resting on a misapprehension of the use and value of infinity.—*John Morland, F.C.S.*

MISCELLANEOUS.

Sale of Poisons. — In the House of Commons on Tuesday the 21st inst. Mr. Clive obtained leave to bring in a bill to regulate the sale of poisons.

Metropolitan Board of Works. Contract for Perchloride of Iron. — The Metropolitan Board have advertised, as will be seen on reference to our front page, for tenders to supply perchloride of iron for deodorising purposes during the summer months of the present year. The perchloride supplied is not to contain less than 1lb. of iron per gallon, corresponding to 2 lbs. 14½ oz. of perchloride and not more than 1 oz. per gallon of free hydrochloric acid. The quantity to be delivered per diem within the Metropolitan area is 5000 gallons or thereabouts, and as much more if necessary on receiving three weeks notice that it will be required.

Substitute for Gutta-Percha.—According to Dr. Kirr, when the bark of the linden is boiled for some time in water it becomes soft, supple, and susceptible of taking all kinds of forms, which it preserves on becoming hard by cooling. This property it preserves after having been used, so that it can be used again for different purposes; according to this, the bark of the linden may be to a certain extent substituted for gutta-percha.—*Annales Méd. de la Flandre Occident.*

ANSWERS TO CORRESPONDENTS.

*** In publishing letters from our correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

E. C. C. Stanford—The Fitzmaurice Light Company have an office in King William Street, E.C.

C. M. Dick.—We shall be glad to hear more on the subject; but we doubt whether our correspondent is right as to the cause of flour heating and souring.

M. W. H.—Forty cells of Grove's battery. It is convenient to have a lantern with an arrangement for adjusting the carbon points.

J. M.—Mr. Hancock vulcanises in several ways. Sometimes he dips the rubber compound into melted sulphur; at other times he sifts sulphur on to the sheets before curing, or he mixes it with the French chalk, and sometimes he mixes sulphur with the solvent.

Phosphate.—1. Impossible, we believe. 2. A soluble alkaline silica can be made by fusing sand with an alkali.

Excelsior.—It is said to be a consequence of catalytic action.

W. J. J.—1. The preparation of chlorodyne is kept a secret. Its use is as an antispasmodic and sedative. 2 Cyanide of potassium will take nitrate of silver stains out.

John Godwin.—We fear it will be impossible to do what our correspondent wishes. It would need a large book, and would be, in fact, a manual of chemistry.

E. H. (York) — *W. S.* (Hanley) — answers next week.

Thomas Salter, F.C.S. — *J. B.* — received.

Mr. F. W. Griffin's book has been received, and will shortly be reviewed.

*** All *Editorial Communications* are to be addressed to the Editor; and *Advertisements* and *Business* communications to the Publisher, at the Office; 12 and 13 Red Lion Court, Fleet Street, London E. C.

THE CHEMICAL NEWS.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Researches on the Organo-metallic Radicals, by M. AUGUSTE CAHOURS.

(*Continued from p. 135.*)

Action of Magnesium on the Iodides of Ethyl and Methyl.—Magnesium, like zinc (which it resembles in many respects), appearing only able to form a single stable grouping of the form MgX, ought only to form a single compound with ethyl and methyl, and experiment shows that such is really the fact. If we place some filings of magnesium in a long and stout glass tube of small diameter, and pour on the metal a few cubic centimetres of iodide of ethyl, a lively reaction ensues, accompanied by a notable elevation of temperature. The action is moderated by affusions of cold water, and when the tube returns to the temperature of the air it is sealed, placed in an oil bath, which is heated to between 120° and 130° C. and the temperature kept within these limits for some hours. A solid white mass is then found in the tube composed of iodide of magnesium, some unaltered iodide of ethyl, and finally a colourless, very volatile liquid, possessing a strong alliaceous odour, which takes fire in the air, and decomposes water with violence when thrown upon it. To separate this substance from the rough product, the contents of the tube are introduced into a small retort previously filled with hydrogen, and distilled at a moderate heat. The iodide of ethyl and the new substance pass over while the earthy iodide remains behind in the retort. By properly managed rectifications of the distillate the inflammable product can be separated from the excess of hydriodic ether. The analysis of the liquid gave the following percentage results:

			Theory.	
C	54·54	4C	24	58·53
H	11·42	5H	5	12·19
Mg	„	Mg	12	29·28
				100·00

The error in the carbon and hydrogen observed in this analysis depends upon the presence of a small quantity of hydriodic ether, of which it is almost impossible to deprive the product. I redistilled the same liquid in a current of hydrogen, and after rejecting the first that came over, the new specimen yielded:

Carbon	55·20
Hydrogen	11·50
Magnesium	—

Here, as in the preceding analysis, the carbon and hydrogen are in excess; but the behaviour of the product with water, its mode of formation, and the manifest analogies with zinc ethyl which it presents can leave no doubt as to its real formula. It corresponds with the oxide of magnesium, ethyl replacing the oxygen.

Iodide of methyl behaves with magnesium just in the same way as the iodide of ethyl: the action is lively; heat is evolved, and a white mass is formed which by distillation is separated into iodide of methyl, and a strongly-smelling mobile liquid, inflammable in the air and decomposing water with the disengagement of marsh gas, separating at the same time flakes of magnesia.

By the action of magnesium on iodide of ethyl, a large quantity of gas is produced. Some of this is absorbed by bromine with the formation of bromated Dutch liquid. The part on which bromine does not act can be partially liquefied by exposure to extreme cold, and the observations of Frankland seem to show the presence of some carbide of hydrogen, C_8H_{10}. The action of magnesium on iodide of ethyl then is exactly like that which zinc exerts on this ether, and may be formularised in a similar manner.

$$C_4H_5I + 2\,Mg = C_4H_5Mg + Mg\,I.$$

$$2\,(C_4H_5I) + 2\,Mg = 2\,Mg\,I + C_8H_{10}$$

$$C_8H_{10} = C_4H_4 + C_4H_6.$$

Aluminethyl.—Aluminium in the cold exerts no action on iodide of ethyl: at the temperature of 100° C. however, the attack becomes very manifest, and by maintaining the mixture for 24 hours at 130° in sealed tubes the reaction is complete. Thick white vapours are seen at the commencement, the metal gradually disappears and a viscous liquid is obtained which fumes abundantly in the air. The contents of the tube placed in a retort filled with hydrogen and distilled yields a colourless liquid with a penetrating disagreeable odour, which presents some analogy with altered oil of turpentine. It fumes in the air, and decomposes water with an explosion, producing alumina and hydriodic acid, as well as an inflammable gas which burns with a pale blue flame. It boils between 340° and 350° C. It contains aluminium, iodine, and carbon and hydrogen in the proportions which constitute ethyl. On analysis, the product gave results which agree with the formula:

$$C_{12}H_{15}Al_4I_3 = Al_2I_3.Al_2(C_4H_5)_3, \text{ or,}$$

12C	72·0	13·78
15H	15·0	2·86
4Al	54·4	10·38
3I	381·0	72·98
	522·4	100·00

When this liquid is allowed to fall drop by drop into a bottle of chlorine or oxygen, it immediately takes fire and burns with a violet flame. The combination belonging to the same type as alumina, we may consider it as formed of an equivalent of iodide of aluminium with an equivalent of aluminethyl. Zinc ethyl attacks it quickly and there is formed the iodide of zinc, and a very inflammable liquid which is probably *aluminethyl*. The iodide of methyl behaves with aluminium just as the iodide of ethyl. A colourless liquid is produced which contains aluminium, iodine and the elements of methyl. Like its ethylated homologue this compound burns in the air, and quickly decomposes water, forming the hydride of methyl.

Glucinium acts strongly on the iodide of ethyl when heated with this liquid in sealed tubes. As in the former cases a solid substance is obtained, which by distillation furnishes a liquid having the power of decomposing water with the disengagement of an inflammable gas; the mode of action appears analogous to that of aluminium.

Stannethyls. — Tin foil is rapidly attacked by hydriodic ether in sealed tubes at a temperature of 140° to 150°. At the latter temperature, by employing 2½ or 3 parts of iodide of ethyl to 1 of tin, the reaction is completed in from 20 to 30 hours. When the tubes are cold, we find in them two sorts of products — a white substance crystallised in long needles and a yellowish mobile liquid — the tin has entirely disappeared. The liquid poured from the crystals again deposits magnificent crystals like the preceding. These are removed with care, and when the liquid deposits no more, it is carefully distilled in a retort furnished with a thermometer. It begins to boil towards 72° or 75°, when the unaltered hydriodic ether passes over. The thermometer soon rises to 230° and remains there a short time. At this temperature an amber-coloured liquid with a very irritating odour passes; then the thermometer rapidly mounts to 245°. The temperature then remains constant, and the product gathered in the receiver solidifies by cooling into a white mass formed of needles crossing one another. The reddish crystalline matter, a very small quantity of which remains in the retort, is iodide of tin. The crystals withdrawn from the tubes and those deposited from the liquid dissolve in warm alcohol, separating on evaporation in beautiul colourless prisms, which are completely deprived of smell by squeezing in blotting paper and recrystallisation. These crystals at 42° melt into a colourless very limpid liquid, which boils between 245° and 246° C. Cold ether dissolves them easily. They are very slightly soluble in cold water, but more so in boiling. The alcoholic solution is immediately decomposed by the sulphate, nitrate, acetate, &c. of silver, forming iodide of silver, and the corresponding salts of the oxide of stannethyl. Ammonia decomposes the alcoholic solution, giving a white amorphous precipitate of oxide of stannethyl, which dissolves in an excess of the precipitant. Oxalic acid and the oxalates form white precipitates. Cyanide of silver gives iodide of silver, and the iodocyanide of stannethyl which remains dissolved in the alcohol and forms on evaporation a crust of crystalline appearance.

When iodide of stannethyl is heated in sealed tubes with its weight of iodine, it is completely decomposed, and the red iodide of tin and hydriodic ether are formed.

$$C_4H_5SnI + 2I = SnI_2 + C_4H_5I.$$

The analysis of the colourless prismatic crystals removed from the tube and purified by several recrystallisations gave results which agree with the formula, C_4H_5SnI.

4C	24·0	11·16
5H	5·0	2·32
Sn	59·0	27·45
I	127·0	59·07
	215·0	100·00

There is formed then by the reciprocal action of tin and the iodide of ethyl, the crystallised iodide of a ternary radical containing carbon, hydrogen and tin, which I shall call stannethyl, a radical which can be eliminated by the intervention of a more electro-positive metal.

Action of Alloys of Tin and Sodium on Iodide of Ethyl. — After having examined the action of pure tin on iodide of ethyl, I propose to study that of a series of alloys of tin and sodium on the same product. The experiments of Wurtz have shown that pure sodium splits up the iodide of ethyl into an alkaline iodide, and a carbide of hydrogen, C_8H_{10} (ethyl), which has been improperly considered as the radical of the ether derivatives of alcohol. Knowing the action of these metals taken separately, it is interesting to see how their alloys behave.

I commenced with an alloy of 98 parts of tin and 2 parts sodium. This alloy had some malleability, but broke on repeated strokes of the hammer. It had no action on the iodide of ethyl in the cold, but heated to 130° C. the decomposition was completed in 20 or 25 hours. As with pure tin, a large proportion of iodide of stannethyl was formed, but with a larger quantity of an irritating oil with a mustard smell, only a small quantity of which is obtained with pure tin.

An alloy of 95 parts tin and 5 of sodium (which can be pulverised) was not immediately attacked by iodide in the cold; by prolonged contact it was acted on. At 130° C. the action was completed in some hours, with the formation of the same bodies as before, but a larger amount of the oily matter with the mustard smell. In both these cases analysis proved that the crystallised matter was iodide of stannethyl.

The oily matter carefully rectified gave two products: a colourless liquid with an etherial odour, which boiled about 75°, a strongly smelling liquid, which boiled between 230° and 240°, and lastly, crystals of iodide of stannethyl. I have not analysed the product which boiled at 75°, all its properties showing that it was hydriodic ether. The other liquid after 2 or 3 rectifications had a constant boiling point, between 234° and 236°. It was a perfectly definite compound, whose analysis agreed with the formula $(C_4H_5)_3Sn_2I$. This liquid then is the iodide of a new radical, corresponding to the oxide Sn_2O_3, and represented by the formula Sn_2E_3.

An alloy of 92 parts tin and 8 parts sodium (which is easily pulverised) is not immediately attacked by the iodide of ethyl; but after some minutes heat is evolved, and the penetrating odour of iodide of stannethyl is perceived. When the mixture had cooled, I placed it in stout tubes, sealed them, and heated to 140° for 24 hours. Two of the tubes having been broken, only a small quantity of gas was given off, but a third flew to pieces. The liquid part of the contents of the tubes was an amber coloured limpid fluid, which began to boil about 200°, and the greater part of which distilled between 235° and 245°. This last portion, deposited crystals of iodide of stannethyl. The first portion carefully rectified between 235° and 238°, also proved to be iodide of stannethyl.

An alloy of 90 parts tin and 10 parts sodium is quickly attacked by iodide of ethyl, even cold, with the formation of a volatile liquid, having a mustard smell. When, however, no action takes place in the cold, the mixture may be heated to 140° for 24 hours. The tubes having been broken, the residue is exhausted with anhydrous ether. The etherial solution evaporated on a water bath leaves as residue a yellowish oil, which swims on a viscous substance of a deeper colour. The oil when rectified gave a pale amber coloured liquid, which boiled between 235° and 238°, and which analysis proved to be the iodide of sesquistannethyl.

Eighty-eight parts of tin and 12 sodium form a crystallised alloy which is quickly acted on by hydriodic ether. The mixture heated for 18 to 24 hours, to 130°, in sealed tubes as before, yields a yellowish brown mass. On

treating this with a mixture of alcohol and ether, and evaporating the solution, a slightly coloured oil is obtained, with an orange coloured viscous mass, in which a few crystals of iodide of stannethyl may be distinguished. The oily matter which forms the greater part of the product analysis shows to be the iodide of sesquistannethyl.

A mixture of 80 parts of tin and 20 parts of sodium (a very beautiful white alloy, formed of a mass of fibrous crystals) is immediately acted on by iodide of ethyl, the greater part of the iodide being expelled, and a dry powder being left in the retort. This powder, with a small quantity of hydriodic ether, is introduced into stout glass tubes, which are sealed, and heated to 120° for 12 hours. On breaking the tubes sometimes but a small quantity of gas escapes, and at other times enough to produce an explosion. The tubes contain a greenish black mass with a powerful odour, which causes a flow of tears and very violent sneezing. The mass is digested with ether for 24 hours, and the liquid is filtered into a glass, which has been previously filled with carbonic acid. In this way a yellowish liquid is obtained, which left by itself in a stoppered bottle, deposits a white flocculent matter that is decomposed by hydrochloric acid, producing a limpid slightly coloured oil with a most penetrating odour.

The etherial solution separated from the preceding is distilled to about an eighth of its original volume. In this state of concentration nothing is deposited; but if half the volume of alcohol be added, and the evaporation continued, a limpid oil is soon seen to separate, which swims on a colourless slightly viscous liquid.

The yellow oil is but slightly soluble in ordinary alcohol. Submitted to rectification it begins to boil about 170° to 175°, and the boiling point gradually rises. Towards the end of the distillation the liquid becomes very cloudy, thick white fumes escape, and metallic tin separates in the form of a melted globule. The same yellow oil exhausted by weak alcohol, and then kept for some time in an oil bath, heated to 170° or 180°, until nothing more distils, has a constant composition. If particles of iodine be thrown on it, the liquid becomes hot, but no gas is disengaged; at the same time the irritating odour of the iodide of sesquistannethyl is manifested.

When the rude product of the preceding rectification is digested with chloride of calcium, and distilled again, a small quantity passes over about 180°; then the thermometer rapidly mounts to about 240°, and remains there for some time; the temperature afterwards rises slowly to 280°, and the last drops of the liquid distil between 280° and 290°. In this second rectification a small quantity of tin separates. The two portions of liquid condensed, are colourless, and perfectly limpid.

The viscous liquid is concentrated over a water bath to about half its volume, and then about twice its volume of water is added, by which means there is separated a very slightly coloured semi-fluid oil, greatly resembling a fat oil in appearance. Heated for some hours in a water bath, and then left in a dry vacuum, this oil is quite transparent. It smells like mould. Heat completely decomposes it. Some tin is separated and a colourless very mobile oil is condensed, which is purified by a new rectification. This oil, which has an etherial odour, very different from that of the other compounds of ethyl and tin, is the *distannethyl* recently discovered by MM. Frankland and Buckton. The thick oil which yielded it is stannethyl.

Distannethyl does not unite directly with oxygen, chlorine, or iodine: it never behaves as a radical: it is an inactive substance, which can exchange a portion of its ethyl for chlorine or iodine, to reproduce compounds of the same type; but can assimilate nothing to form compounds of a higher order. This fact demonstrates the persistence of the grouping SnX_2, which we cannot go beyond.

The yellow oil, but slightly soluble in ordinary alcohol, furnished on analysis results which, converted into percentages, were as follows:

	I.	II.	III.			Theory.
C	34·72	35·34	34·88	12C . .	72	35·12
H	7·20	7·45	7·36	15H . .	15	7·31
				2Sn . .	108	57·57
					205	100·00

This product must then be considered as a sesquiethylide of tin, and consequently its formula will be written $Sn_2(C_4H_5)_3$. It unites directly in the cold with oxygen, chlorine, bromine, and iodine, reproducing the oxide, chloride, and iodide of sesquistannethyl.

TECHNICAL CHEMISTRY.

On the Use of Sewerage.[1]

The transport of the sewage matter to a distance from the metropolis has become with the present arrangements a matter of paramount necessity; but the accomplishment of that end ought by no means to stifle the inquiry as to whether some means might not be devised for rendering the same material available for useful purposes.

If the citizens of London were as fully impressed as they ought to be with the importance of this subject, if they could realise the enormous pecuniary loss they are at present sustaining by the system pursued, they would not quietly acquiesce in the report of those chemists who have expressed doubts as to the practicability of employing their sewerage for agricultural purposes, but would persevere in putting both science and capital into requisition until the difficulties had been at length surmounted.

Nor would it be consistent with ordinary prudence to depend upon a foreign, precarious, and probably exhaustible source, for the supply of that material which nature has placed within the reach of every individual in the excreta which he himself furnishes. On the other hand, the other class of reasoners who rely upon the subsoil for restoring at any time and to any extent the loss occasioned by the transfer of the constituents of our crops to our great cities, lean more upon theory than it would be safe to do in matters of such momentous importance.

It may be demonstrable indeed that the crust of the globe, take it all in all, contains an inexhaustible supply of the phosphates, and it may be also true that certain land has been made by diligent tillage alone to yield up to the crop a sufficiency of this ingredient for a period of time, which although nothing compared to the duration of the community in which the trial was made, seems to our limited views as something considerable. But experiments are yet wanting to show what amount of labour, what description of treatment, what period of time, what concurrence of atmospheric conditions, would

[1] From a Lecture on Sewerage, with particular reference to Baron Liebig's remarks relative to the system of disposing of it adopted in the principal cities of this country; delivered on February 3, 1860, in Oxford, by Charles Daubeny, M.D. F.R.S. Professor of Rural Economy in that University.

be required under ordinary circumstances to effect the desired end; and indeed the investigations made elsewhere might lead us to infer that the means employed at Lois-Weedon, even if they could be adopted on a sufficiently large scale elsewhere, would in the majority of cases be insufficient to enable us to dispense with manure. Although the supply theoretically speaking may be inexhaustible, it is certain that the labour and difficulty of obtaining it must increase in a very rapid ratio with its distance from the surface, so that whatever lies below the reach of the subsoil plough may be regarded for practical purposes unavailable.

No doubt the mineral constituents which render a virgin soil so productive were derived from the decomposition of the subsoil underneath, but we know not how many centuries may have been required to bring about this result, and might therefore as well calculate upon making good the consumption of our coal fields, the accumulation of countless ages of vigorous vegetation, by the decay of the timber or herbage now growing upon the surface, as to reckon upon bringing back an exhausted soil to the fertile condition in which it had been handed over to us by nature, through the medium of any transient application to it of mere human industry.

The experiments hitherto made upon subsoiling scarcely warrant our anticipating any sudden restitution of its pristine fertility to the soil, by bringing up portions of the subjacent rock to the surface, for where that has been done incautiously, or on too large a scale, the very opposite result is said to have ensued.

And this is explained by the condition in which the phosphates, as well as the alkaline ingredients, exist in the rock, before they have been made accessible to the influences of atmospheric agents.

In a memoir on the Rotation of Crops, read before the Royal Society, which was honoured by being made the subject of their Bakerian Lecture for 1845, I communicated the results of 10 years successive experiments upon various crops planted under my own direction within the precincts of the Botanic Garden, which led me to at least one important conclusion, namely, that a soil may continue to retain a large amount of all the necessary constituents of a plant, and yet be unable to impart them to it in sufficient quantities, owing to the condition in which they were retained in combination.

Thus after 10 years' cropping, at which time the soil for many sorts of plants appeared to have approached exhaustion, I found by analysis that 6 lbs. of phosphate of lime, equal to about 3 of phosphoric acid, existed in every 100 square feet of soil taken to the depth of 3 feet from the surface, a quantity which would have sufficed for at least 13 more crops of barley, as abundant on the average as those which had been already obtained from the same plot.

And in like manner I found that there was magnesia enough for 34 crops, and of potass for 15.

But the greater part of these ingredients, although they were separable from the rest of the soil by digestion in muriatic acid, was not acted upon by water containing carbonic acid, the latter only extracting $\frac{1}{10}$ths of a grain of earthy phosphate from 5 lbs. of the soil, an amount equal to $\frac{1}{11000}$th part; so that whilst the real quantity as determined by muriatic acid was $\frac{1}{1100}$th part of the soil, that separated by water and carbonic acid amounted to $\frac{1}{10}$th the part of the latter quantity.

These and similar investigations led me to what I consider the most valuable conclusion suggested in the memoir, namely, that the constituents of the soil may be divided into those latent or dormant, and those active or available, it being reasonable to conclude that a substance which cannot be extracted by water containing carbonic acid, the method which Nature adopts, but only by muriatic acid, ought to be regarded as immediately applicable to the uses of the plant.

Before therefore we can predict with any certainty what amount of time it will take to bring an exhausted soil into a fertile condition we must know not only what amount of phosphoric acid and of alkalies it contains, but also what means will avail for converting its dormant constituents into active ones.

On this point I conceive experiments are much wanted; but as they require, like many others relating to agriculture, a considerable lapse of time to complete, as well as a large expenditure of labour, they lie beyond the reach of a person arrived at my time of life, and unprovided with a suitable staff of assistants for carrying on the necessary investigations.

Whatever might be the conclusions to which such experiments conducted, they could not fail to be of the highest practical importance to the public. Should it, for instance, turn out that in the case of ordinary rocks the time and labour requisite for bringing into an available form the constituents of our ordinary crops is so great, that, although theoretically possible, it would in a practical sense be hopeless, in the event of the supply of guano and mineral phosphates falling off, to attempt restoring fertility to a thoroughly exhausted field by such methods as we could put into operation, then, indeed, the future of British agriculture presents a gloomy prospect, unless an entire change in the system of disposing of our town sewerage be speedily resolved upon.

Nothing less than a return to the old method of cesspools, still in use in most continental cities, will [in that case] suffice, to prevent those parts of the country which feed our vast metropolis from sinking gradually into a condition of irremediable sterility.

A country like Great Britain, teeming with population, and already occupying every nook and corner of the land, which Nature has not consigned to barrenness by unfavourable conditions of temperature, elevation, or physical structure, cannot revert to the same expedient which was adopted by our brethren in the New World, who, when they had exhausted the resources of one plot of ground, moved on immediately to the next.

But to take a more hopeful view of the case. Supposing it to be proved that in most instances a calculable amount of labour and capital expended upon an exhausted soil will in the course of time elicit the latent treasures of the subjacent subsoil, and bring it into that condition which it has been, and may be, maintained, so long as guano and superphosphates continue to be supplied.

Still we must recollect that the difficulty of restoring to the land its pristine fertility will go on in an increasing ratio on each succeeding occasion; 1st, because we shall have every time to bring the materials from a greater depth than heretofore, and therefore with a greater amount of labour; and 2ndly, because the constituents brought into an available or active condition will, on each repetition of the process, be diffused over a larger amount of inert matter.

It must be borne in mind, that the fertility of a soil depends, not upon the absolute quantity of phosphates, soluble silicates, and the like, present in each acre of ground, but upon the proportion in quantity they bear to the material through which they are diffused.

Supposing therefore, a soil 3 feet deep to be thoroughly exhausted of its fertilising materials, we cannot expect to restore it to its pristine state by converting another 3 feet of the subsoil into the same condition, into which it had been brought in the first instance by natural agencies, because the phosphates, &c. present in the latter will have to be diffused over twice the quantity of earth as before.

And after all should we not, even at the best, be acting like the proprietor, who, because he had reasonable hopes that his estate contained within itself a vein of precious metal which required only capital and labour to bring to the surface, were to throw into the sea as superfluous his bags of gold, already coined into money, and made available for all the purposes of life; or like the possessor of a colliery of unknown extent, who squandered away in the metropolis the wealth he had derived from his mine, without laying up any provision for the day at which the source of all his revenue might be worked out.

It is enough for us to know that from the disposal of the sewerage of London alone we are incurring a national loss of more than a million sterling; that the principal source from which the lands of this country are maintained in their present state of productiveness is likely in a few years to be dried up; that we are at present in great measure in the dark as to the means by which this loss could be supplied; and therefore that it is of vital importance for the nation at large to use every effort in its power to find some useful application for its excrementitous matters, as well as to determine what other means could be resorted to, for providing against the day when agriculture may have to fall back upon its own unassisted resources through the failure of all supplies from without.

At any rate it must be admitted that whatever improvements have been effected or are in contemplation with regard to the disposal of our sewerage, bear reference rather to the sanitary than to the economical phase of the question; for it will be seen from the statements given in the preceding part of my lecture, that except in a few isolated cases, such as Rugby, the only portion of the excrementitious matters which it is attempted to preserve is the solid, which stands far the lowest in the scale of agricultural value. No doubt it is essential to the health of our cities that the latter should either be deodorised or removed to a distance from the population; and it may be important that neither the one nor the other of these proceedings should be neglected. Still, we can never expect to recover any considerable portion of the value of our sewerage, so long as the liquid portion is suffered to run to waste.

Nor is it as yet clearly made out, how, consistently with the present arrangements, so universal in our large cities, we can procure the latter in a form sufficiently concentrated for general agricultural purposes. All we can hope to do at present is to apply it as a means of irrigation, thus obtaining from the luxuriant meadows which its application to the herbage would create, the fittest material for the maintenance of those herds of sheep and cattle, which are consumed by the population of our great cities, and therefore the best compensation for the loss sustained by the provinces which supply them with food.

If, therefore, there be any truth in the views which Baron Liebig has propounded, and of which I have undertaken in this lecture to become the humble expositor, the time is drawing on when the people of this country, if no improvements in our modes of concentrating our sewerage be discovered, will have to revert to the practices of communities whom, in the pride of their self-conceit, they consider less advanced in civilisation than themselves, and even to admit that after all our boasted progress in the arts, the oldest and least improvable nation on the face of the globe presents the nearest approach to a correct system in the disposal of its excrementitious matters; or else they must find, within a certain area of the metropolis, a sufficient tract of meadow land to receive the diluted contents of the sewers, and to absorb all the valuable materials which they carry with them.

I am fully aware of the difficulties which attend either scheme, but I cannot but think that if the nation were alive to the importance of the subject, and were conscious that in a few years the necessity of grappling with it must force itself upon its consideration, it would not be content in the mean time to derive its information on a matter of such importance from individuals only, and those often foreigners, but would regard the question at issue as one not less deserving the attention of government than any of those other subjects which come within the cognisance of parliamentary committees.

PHARMACY, TOXICOLOGY, &c.

On Quinio or Rough Quinine, by M. Batka.[1]

A substance is known in the Brasils under the name of quinio, which is extracted from the fresh bark of the cinchona by lime and then from the lime by alcohol. It is very rich in quinine, and it is only necessary to boil it with dilute sulphuric acid to obtain an abundant crystallisation of pure sulphate of quinine.

Quinio is a yellow body of a resinous appearance and of a bitter taste. It is insoluble in cold and but slightly soluble in boiling water. It is very soluble in alcohol and ether separating partially from the latter by exposure to the sun. Water precipitates the alcoholic solution. It is almost entirely soluble in weak sulphuric acid, from which soda precipitates it of a dirty white colour, the precipitate assuming the appearance of a resin. A beautiful white sulphate however may be prepared from it.

Quinio is free from cellulose; when heated it gives off an odour something like cinnamine, and burnt leaves a light residue of carbonate of lime. It resembles a good deal the quinoidine of Liebig, but is much purer than the quinoidine of commerce.

Substitutes for Quinine.[2]

The Society of Pharmacy of Paris proposed as the subject of a prize, the artificial formation of quinine or the discovery of a substitute possessing equivalent febrifuge properties. Nine essays were sent in, and at the sitting on November 2, 1859, M. Buignet gave an account of the results of their examination. The nine essays related to as many different substitutes.

1. A common indigenous plant of which the author described the properties, but did not give the name nor even any description of its botanical or chemical characters.

[1] *Chem. Centralblatt*, 58, s. 913.
[2] *Journal de Pharm. et de Chimie*, Fév. 1860.

2. On the resin of *plantain* such as can be obtained from the plantago major, minor and lanceolata by means of alcohol and proper treatment.

3. On the bark of the *cail-cedra*, khaya senegalensis.

4. On a substance obtained from leukol by particular treatment, the description of which was so vague that the commission could not repeat it.

5. On the tannate of peroxide of iron, which is nothing more than writing ink.

6. On the tincture of an unknown plant.

7. On various substances simply enumerated without any pharmaceutical or medical account.

8. On a particular preparation which the author regards as modified cinchonine, and which appeared to him a febrifuge equal to quinine.

9. On the ferrocyanide of sodium and salicine.

But a few of the authors had fulfilled the condition which required them to send a specimen of at least 250 grammes of the new febrifuge. Those which had been sent had been tried in the military hospitals at Rome, Ajaccio and Perpignan, but the reports from medical officers of the army had not supported the results announced by the authors. The Council decided not to grant the prize at present, but to leave it open until the 1st of July 1861. The great progress made in organic chemistry, and the constantly increasing number of alkaloids made artificially, leaves no doubt that the study will lead to the desired solution.

The prize of the society is 6000 francs, to which the Minister of War will add 4000 francs.

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

Friday, 17 February, 1860.

JOHN WEBSTER, *M.D. F.R.S. in the Chair.*

On the Influence of Science on the Art of Calico-Printing, by PROFESSOR F. CRACE CALVERT, *F.R.S. F.C.S. &c. &c.*

CALICO printing has partaken of the general progress of the manufacturing arts; and this can be easily understood when it is remembered that it is based upon three distinct branches of knowledge — mechanics, art, and chemistry. Not being acquainted with machinery, I shall not attempt to describe the various mechanical improvements and machines which have been introduced; but shall confine myself to stating that ever since 1815, the period at which it was first extensively employed in the printworks of Lancashire, machinery has gradually supplanted hand labour, and thereby immensely decreased the cost of production, at the same time that it has improved the beauty and precision of the results obtained.

Pencilling and Block-Printing. — During the early part of this century, the production of designs upon calico was performed by means of hand blocks, made of sycamore or peartree wood, two or three inches thick, nine or ten inches long, and about nine broad. The face of the block was either carved in relief into the desired pattern, like ordinary woodcuts; or the figure was formed by the insertion edgewise into the wood of narrow slips of flattened copper wire, and the patterns were finished by the hand labour of women with small brushes called pencillings. Owing to a strike amongst the block-printers in 1815, to resist the threatened introduction of machinery, great efforts were made on the part of the employers to render themselves independent of hand labour; and the result has been the gradual introduction of cylinder printing. Without entering into the intricate details of the steps by which the art of engraving has been carried to its present high degree of perfection, I shall simply give an outline of the successive improvements alluded to.

Engraving. — The first kind of roller used was made by bending a sheet of copper into a cylinder, soldering the joint with silver, and then engraving upon the continuous surface thus obtained.

The second improvement consisted in producing the pattern on copper cylinders obtained by casting, boring, drawing, and hammering. In this case, the pattern is first engraved in intaglio upon a roller of softened steel, of the necessary dimensions. This roller is then hardened and introduced into a press of peculiar construction, where, by rotatory pressure, it transfers its design to a similar roller in the soft state, and the *die* being in intaglio, the latter, called the "*mill*," is in relief. This is hardened in its turn, and by proper machinery is made to convey its pattern to the full-sized copper roller. This improvement alone reduced the cost of the engraving on copper rollers many hundreds per cent.; and, which is of far greater importance, made practicable an infinite number of intricate engravings which could never have been produced by hand labour applied directly to the roller.

A further improvement was made by tracing with a diamond on the copper roller, covered with varnish, the most complicated patterns by means of excentrics, and then etching.

The combination of mill engraving with the tracing and etching processes naturally followed, adding immensely to the resources of the engraver and printer in production of novel designs.

Another development of this art is the tracing of patterns on the surface of rollers, which has been effected by machines constructed on the principle of the pentagraph. Although this invention dates from 1834, still it is only of late years that it has been successfully applied.

But if mechanical art has greatly assisted the engraver, chemistry has rendered him equally important services, by enabling him to abandon costly and cumbrous modes of impressing by force the designs on the cylinder, substituting for them a great number of etching processes. By some of these processes, as by every other addition to the resources of the engraver, an entirely new and beautiful class of engraving is produced, unattainable by any other known means.

A very recent improvement is highly interesting in a scientific point of view. It is the application of galvanism to the diamond tracer. By combining the galvanic action with the excentric motion, most beautiful and delicate engravings can be produced. This is effected by tracing the pattern with a varnish on a zinc cylinder, which is so placed in the engraving machine, that as a needle passes over its surface, and comes in contact with the zinc, the galvanic current is established, and by simple machinery, causes the diamond to trace the corresponding pattern on the copper roller. The communication is so rapid and so precise, that this invention of Mr. Gaiffe, of Paris, bids fair to produce very important results. Galvanism is also made use of, for producing effects on roller surfaces by depositing copper thereon.

To give an idea of the extraordinary influence which the introduction of machinery and improvements in engraving have had in cheapening the cost of printed calicoes, I may state that large furniture patterns, such as are required for Turkish, Egyptian, and Persian markets, into which sixteen colours and shades enter, would have cost formerly from 30*s.* to 35*s.* per piece, because they would have required 16 distinct applications of as many different blocks, and would have occupied more than a week in printing, whereas the same piece can now be printed in one single operation, which takes three minutes, and costs 5*s.* or 6*s.* So rapid is the progress of one branch of manufacture in connection with another, that it has only recently been possible to produce the rollers capable of performing this operation, that is to say, cylinders of copper 43 inches in circumference by 44 inches long. For light styles of printing, the time reqiured to print a piece of 36 yards is not more than one minute.

Chemistry. — But the discovery which has exercised more influence than any other on the progress of calico printing, is the application of *chlorine* gas as a bleaching agent. Previously to the employment of this gas (chiefly as bleaching powder), the imperfect bleaching of a piece of calico required six weeks; and as it had to be exposed to the action of the atmosphere, a large surface of land was required. Further, at that time bleachers had to use potashes imported from Canada; whereas at the present time, thanks to the progress of chemical knowledge, not only is soda-ash manufactured in this country, but by the application of bleaching powder calicoes are much better bleached in 24 hours than they were formerly by a six weeks' exposure to the atmosphere; and even when an extra cleaning and whiteness is required, as for madder goods, only two days are necessary. The aid of machinery renders possible the continuous process; that is to say several hundred pieces of grey calico are sewn together, end to end, and made to pass from one operation to another without any pause, until they are bleached. So rapid and economical is this method, that the cost of bleaching a piece of calico does not exceed one or two pence. Chlorine again renders a great service to the calico printer, by enabling him, after his *madder goods* have been produced and soaped, to obtain fine whites without the necessity of exposing them for several days in the meadows to the action of the atmosphere. In fact the discovery of *garancine* and *alizarine*, and their application to calico printing, have facilitated the production of madder styles at very low cost, as the whites of such goods require no soaping, and only a little bleaching or cleaning powder.

Cotton has this peculiarity as distinguished from wool and silk, that it will not fix any organic colour excepting indigo, without the interposition of a mordant, which is generally a metallic oxide or salt. The two most important discoveries in connexion with this necessity of calico printing were, first that made in 1820, by Mr. George Wood, of Bankbridge, who found out the means of preparing calicoes with peroxide of tin, which enabled printers to produce a large variety of prints called *steam goods*; and secondly that of Walter Crum, Esq., F.R.S., who, in a paper presented to the British Association at Aberdeen, in 1859, showed that the tedious process of ageing madder mordants for three or four days might be dispensed with by passing the goods during a quarter of an hour through a moist atmosphere, at a temperature of 80° to 100°, where the mordants absorb the required quantity of moisture, and then rapidly undergo the chemical changes necessary to fit them for producing the black, purple, lilac, red, pink, and chocolate colours, which the madder root will yield immediately in the dyebeck, according to the nature of the mordant previously fixed in the cloth.

As it is impossible in the brief space of an hour to convey an idea how various colours are produced on prints, I shall confine my remarks to illustrating the interesting fact that abstruse science has brought to light various substances which have lately proved valuable accessories to the resources of the calico printer. Thus Dr. Prout, some thirty or forty years ago, made the curious discovery that uric acid possessed the property of giving a beautiful red colour when heated with nitric acid and then brought into contact with ammonia. The substance thus obtained was further examined by Messrs. Liebig and Wöhler, in a series of researches which have been considered as amongst the most important ever made in organic chemistry; and this substance they called *murexide*. In the course of these investigations they also discovered a white crystalline substance called alloxan. For twenty years both these substances were only to be found in the laboratory; but in 1851 Dr. Sasc observed that alloxan when in contact with the hand tinged it red. This led him to infer that alloxan might be employed to dye woollens red, and further experiments convinced him that if woollen cloths were prepared with peroxide of tin, passed through a solution of alloxan, and then submitted to a gentle heat, a most beautiful and delicate pink colour resulted. Subsequently murexide was employed and applied successfully by Mr. Depouilly, of Paris, to dyeing wool and silk, and to printing calicoes, by the aid of oxide of lead and chloride of mercury as mordants; but the great obstacle to its extensive use was the difficulty of obtaining uric acid in sufficient quantity for its manufacture. The idea soon occurred to chemists to extract it from guano, and this is the curious source whence the chief supply of uric acid is obtained, and which enables Edmund Potter, Esq. and other printers to produce the colour called Tyrian purple.

Another example will be found in the successive scientific discoveries which have led to the discovery of the recently popular colour, *Mauve*. Lichens, which have been the subject of extensive researches on the part of Robiquet, Heeren, Sir Robert Kane, Dr. Schunck, and especially of Dr. Stenhouse, have yielded to those chemists several new and colourless organic substances, which, under the influence of air and ammonia, give rise to most brilliant colours, and amongst these are orchil and litmus. Dr. Stenhouse, in a most elaborate paper, published by the Royal Society in 1848, pointed out two important facts; first, that the colour-giving acids could be easily extracted from the weed by macerating it in lime water, from which the colouring matters were easily separated by means of an acid; and, secondly, the properties of certain colouring acids, which gave M. Marnas, of Lyons, the key which enabled him to produce commercially from lichens a fast mauve and purple which up to 1857 had been considered impossible of attainment.

The commercial production, by Mr. W. H. Perkin, of another purple, at the same time, is not less interesting. Some thirty or forty years ago, Dr. Runge obtained from coal-tar six substances; amongst which was one called *Kyanol*, which substance was thoroughly examined by Dr. A. W. Hofmann, who proved it to be an organic alkaloid, and identical with a substance known by the name of aniline. Owing to the subsequent study of this substance by that eminent chemist, and the discovery that it yielded a beautiful purple colour when placed in contact with bleaching powder, his pupil, Mr. W. H. Perkin, was induced to make experiments, with a view to producing commercially a fast purple, in which he succeeded, and secured it by a patent in 1857. The process devised by this chemist is exceedingly simple. It consists in oxidising aniline by means of bichromate of potash and sulphuric acid. I shall not attempt to give any further details on this subject, as they have been very ably described by Mr. Robert Hunt in the *Art Journal*.

More recently Mr. Renard found a method of producing, also from aniline, by means of chlorine compounds, a most splendid rose colour, called by him *Fuchsiacine*; and, within the last few months Mr. David Price has also succeeded in producing from aniline, by the employment of peroxide of lead, either a fast purple, or a pink, called by him Roseine, and a fast blue, according to the mode of operating. All these colours require some special mordants to fix them on calicos or muslins; and the beautiful specimens which I have the honour to lay before you I owe to the kindness of Messrs. James Black and Co., and Messrs. Boyd and Hamel, of Glasgow, who have fixed the last-mentioned colours by means of azotised principles, such as albumen, lactarine, &c.

I cannot give a better idea of the immense magnitude of the calico-printing trade than by quoting the number of yards exported, which amounted in 1858, to 785,666,473— and give a price value of 13,147,280*l*.

I cannot conclude without expressing also my thanks to Mr. Wood, of the firm of Wood and Wright, and Mr. R. Leake, of the firm of Lockett, Sons, and Leake, Messrs Dalglish and Faulkners, for the numerous and valuable specimens which they have kindly sent me to illustrate my discourse; and especially to Mr. W. Grant for the loan of a most interesting book, containing the patterns belonging to the late firm of Sir Robert Peel, Bart., which bears the date of 1790.

SOCIETY OF ARTS, 22 *Feb.* 1860.

SIR T. PHILLIPS, *F.G.S. (Chairman of Council) in the Chair.*

On this occasion Mr. S. SQUIRE BAXTER undertook to explain to the meeting the general characteristics of a *New Lime Light*, and read a somewhat desultory paper upon the subject, the light itself being exhibited during the greater part of the evening. Our readers are doubtless aware that a "Company" has been formed for the purpose of developing the patented improvements of Mr. G. H. Bastable in this direction, and that the principle of this so-called "New Light" differs but in some trifling mechanical details from the oxy-hydrogen arrangements of nearly forty years ago. The first half of Mr. Baxter's paper was devoted to general remarks upon the moral, social and commercial advantages of increased supplies of light, and to notices of the chief methods adopted for street and domestic illumination up to the present time. At length he said,—

"It was found by Drummond that many substances were capable of producing light in conjunction with gases, but that of all those which were available for the perfect combustion of the gases, chalk lime was the most suitable material for the purpose, and hence the name (of the "Lime Light." It was also the cheapest and most easily attainable in any locality. It was likewise found that several gases, compounds of hydrogen, might be successfully employed in combination with oxygen gas as well as pure hydrogen.

Pure hydrogen gas obtained from zinc and diluted sulphuric acid, offers facilities in cases where caburetted hydrogen, as supplied by the gas works, cannot be readily procured, but coal gas where available, is a most desirable substitute for the ordinary applications of the light.

The product resulting from the generation of pure hydrogen gas from zinc and sulphuric acid is sulphate of zinc, which from the extensive demand for it as a material used in the manufacture of paint, &c. will always find a ready sale at a price which will leave the cost of the gas in favourable contrast with other gases which may be used for the purpose."

Other sources of hydrogen were then noticed, and the lecturer proceeded to describe the second ingredient of the light— oxygen,—naming the various substances from which that gas may be obtained, but giving the preference to the peroxide of manganese. As some rather extraordinary statements are made in this place we give the original:—"The peroxide of manganese requires simply to be placed in a retort, and raised to a red heat, when the oxygen gas is freely disengaged. So soon as the gas ceases to be evolved from the manganese (which can only be effected practically to the extent of about 11 per cent., although it contains at times 80 per cent.), the residuum, the deutoxide or sesquioxide (!) of manganese may be drawn from the retort, and if thrown into water, or exposed at a high temperature to the action of the atmosphere, it will attract oxygen with great avidity, and thus this refuse becomes revivified or resumes its former state of a peroxide, fitting it by this operation for a repetition of the distillatory process. This peculiar property of the deutoxide of manganese (of rapidly absorbing oxygen from the surrounding air, or other oxygenated bodies brought into contact with it) gives to this substance a great commercial value as a material for producing oxygen gas; for since the actual consumption of the manganese is thus limited by the quantity necessary to provide for the supply of gas during the time required for the revivification of the exhausted material, a comparatively small stock only will be needed to compensate for the unavoidable waste consequent on this mode of operating upon it. In addition to this source of economy, the demand for the deutoxide of manganese for chemical purposes in glass-making, bleaching, and other processes in the arts, presents a means by which the residnum may be disposed of at a price which will leave the cost of the gas merely nominal."

Upon such observations as the preceding, comment is by no means a pleasant task, so, as all readers will at once notice the palpable errors and confusion of chemical nomenclature contained therein, to say nothing of dictional backslidings, we will refrain from playing the critic too severely by passing on to the mechanical arrangements, where our author is a little more at home. The *improvements* upon which the "Lime Light Company" have staked their existence Mr. Baxter thus describes:

"To effect the desired object of protecting the lime from crumbling away, and of ensuring a practically unlimited supply, the simple expedient of enclosing the lime in a case or guard, both above and below the point of ignition, was resorted to, exposing only such portion of its surface as was required for the action of the gases; and by giving to the lime so enclosed a movement within the tube, the retention of the broken portions of lime was insured, until by simple means they were allowed to escape without detriment to the light, or were replaced by a fresh supply in as simple a manner as the cotton wick of an Argand lamp, thus effecting with the perfect continuity of the light for any reasonable period (a fortnight or more if necessary) of time, the maximum brilliancy of light.

So simple are the mechanical appliances for producing these results, that they fall as much within the compass of the ordinary attention bestowed on such objects as an ordinary lamp.

Thus, it results that lime, for any reasonable period, may be supplied to the lamp, producing a continuous and steady light so long as the gases and lime are supplied to it.

The two gases are kept under equal and uniform pressure in gas holders, which are connected with the lamp by pipes. The gases are kept separate until they have passed the regulating taps, and then they are mixed, and pass together, through wire gauze protectors (to prevent the regurgitation of the flame), into the jet tube, from the orifice of which they are projected together on to the surface of the lime, producing an intense light.

The carburetted hydrogen gas, where it cannot be obtained from a contiguous gas main, may be procured from oil or Leslie's gas liquid at a cheap rate, the process of generating it being one of extreme simplicity, as it does not involve the necessity for the extensive appliances of a gas works, which, though to a great extent unobjectionable for manufacturers of gas, are nevertheless unsuited for private purposes."

Some remarks upon the peculiar capabilities of the "lime light" and the various advantages to be derived from its use, here succeed, and the paper concludes with the question of expense:

"The cost of the light may be stated, in general terms, to be one half the price of its equivalent gas light, all expenses being taken into consideration.

It has already during the last eighteen months been used at various places, and is now being permanently exhibited on the south landing stage at Liverpool, and the members of the society will, in the course of a few days, have an opportunity of witnessing its capability on the first half of the new Westminster Bridge.

The following is a tabular statement of the comparative value of light from various substances, compiled from data derived from a series of experiments made by Mr. E. V. Gardner, at the Royal Polytechnic Institution, Regent Street."

Description of Material.	Particulars of Burners, &c.	Value in Wax Candles, 6 to the pound.	Consumption of Material per hour.	Units of Cost.	Cost per hour of Light of equal intensity.
Lime light, with coal gas	Jet $\frac{1}{10}$ in. diam.	758	ft. 7·2 ox. 7·8 gas.	9	d. 1·00
Lime light, with hydrogen	" "	1167	6·53 ox. 12·4 hy.	10	1·11
Argand gas light	" 15 holes	20·18	0·50 cub. ft.	17	1·88
Fish-tail "	" No. 1	0·7	2·41 "	18	2·00
Ditto "	" No. 4	6·66	5·00 "	40	4·44
Moderator oil "	" 1 in. diam.	19·5	860 grains.	42	4·66
Argand "	" $\frac{15}{16}$ in. diam.	14·15	697 "	97	10·22
Bude "	" "	151·25	4000 "	117	13·00
Wax candle "	6 to the pound.	1	130·5 "	599	66·55

This table of experimental values must, we suspect, be viewed with considerable caution, particularly if based upon the "peculiar property" of the "deutoxide or sesquioxide of manganese" before alluded to.

Dr. Letheby opened the discussion by totally disagreeing with the author of the paper on the subject of cost. According to his (Dr. L.'s) calculation, the oxygen if derived from the chlorate of potassium would cost 9*l.* 12*s.* per 1000 cub. feet, while ordinary coal-gas was now produced at the rate of 1*s.* 6*d.* for the same quantity, and he considered that upon this estimate the *lime light* would be far more expensive than gas for an equal amount of light. Even upon the patentee's estimate of 3*l.* 15*s.* for the above quantity of oxygen, Dr. Letheby thought that the new light would cost fully twice as much as coal-gas. Besides this the light was too intense to be pleasant, which was calculated to bring on paralysis of the retina. The revivification of the oxide of manganese was distinctly an impossibility, and the speaker finally characterised the light as the most expensive that could be adopted, and one of the most dangerous to the eyesight of those using it.

Dr. Bachhoffner said that he had probably had more experience with this light than any other man, having used it daily for more than twenty years; he believed that for ordinary purposes of illumination the lime light would fail completely, at the same time he could not quite agree with the views of Dr. Letheby, who had overrated its cost. The light exhibited he did not consider satisfactory, nor was it at all suited for the oxyhydrogen microscope — the pressure was far too low. According to Dr. Bachhoffner, with a water-pressure of 13 inches, he obtained a light equal to 25·9 Argand burners, each containing 6 feet of gas per hour, the cost of the lime-light (with oxygen and coal-gas) being 1*s.* 10½*d.* per hour, while the same amount of light from ordinary gas burners for a similar period would cost 8½*d.* only. He condemned the use of chlorate of potassium as both expensive and injurious to brass work — denied that exhausted peroxide of manganese could be restored, or possessed any marketable value, and said he had seen hundreds of tons of sulphate of zinc thrown away, as nobody would be at the trouble of fetching it.

Various observations were made by different speakers which want of space forbids us to transcribe, but we may briefly note that Mr. Lambert said he formerly knew a German chemist, Mr. G. Michiels, who obtained oxygen from the atmosphere by passing heated air over hydrate of baryta until the latter had absorbed its maximum of oxygen, when at a higher temperature the gas was again evolved, and could thus be collected. Mr. Michiels told him that oxygen could be obtained by this method, at about the same cost as coal-gas, but he was unfortunately killed by a laboratory accident before his plans were fully developed.

The meeting terminated with the usual vote of thanks.

CORRESPONDENCE.

Nutritive Properties of Aluminised Bread Food.

To the Editor of the Chemical News.

Sir,—At a discussion on the "Chemical Properties of Milk," reported in your impression of the 18th Feb. Dr. Routh states,—

"That the effect of alum, which nearly all bread contains, is to fix phosphoric acid in a perfectly insoluble form, and thus to deprive the infant of an ingredient essential for its nourishment.

"That aluminised bread food was as sure a poison as opium or any other poison, if long persisted in.

"That the absence of chloride of potassium (a salt absolutely required for the progress of the cell growth) in vegetable food, is an objection to its use."

It surely cannot be allowed that statements so calculated to mislead should go forth to the public unchallenged, more especially when made by so eminent an authority as Dr. Routh.

The effect of alum is not to form under these circumstances an insoluble compound with phosphoric acid; for although such compound is insoluble in water *per se*, yet it is perfectly soluble in the presence of a large amount of organic matter.

If an insoluble compound were formed it would not have the effect of withholding the supply of phosphoric acid, inasmuch as only a very small proportion of the phosphoric acid contained in the bread would be sufficient to combine with all the alumina, even if the bread were adulterated to a much greater extent than is ever found to be the case; for whilst the alumina would not exceed 1·4 grs. in the pound, the quantity of phosphates would be about 70 grs.

The adulteration of flour with alum is by no means so common as is generally supposed. In those cases in which it is used, from 1 to 2 oz. is mixed with 56 lbs. of flour. Take however the larger quantity, say 2 oz. Bread made from such flour would not contain more than about 14 grains of alumina in the pound, and assuming that alum possesses all the injurious properties which have been attributed to it, surely it cannot be classed with "opium or any other poison."

I am not aware upon what grounds Dr. Routh makes the assertion respecting the necessity of chloride of potassium for cell growth, but such a conclusion can scarcely be drawn from the fact of the cell formation containing this salt. It is well known that in the vegetable kingdom chloride of sodium can take the place of chloride of potassium, and there appears to be every reason to believe that it is perfectly immaterial whether the potash supplied in food exists as chloride, or as phosphate, or sulphate (of which latter salts all vegetables contain abundance), more especially where these are associated with chloride of sodium.—I am, &c.

Common Sense.

The Atomic Theory.

To the Editor of the Chemical News.

Sir,—I should be very sorry if Mr. Reynolds were to think the atomic theory a favorite of mine; on the contrary I only hold it until I am acquainted with a better one to which I can flee. I shall be very much obliged to Mr. Reynolds, or any one else who enlarges on this subject, feeling confident that the path to truth is much cleared by our not being ashamed of our opinions. To the point. The atomic theory (divested of those relations to chemical compounds which were added by Dalton) merely supposes matter to be a congregation of indivisible atoms. From this simple hypothesis there can be deduced these three corollaries:

Cor. I. Atoms are perfectly hard (since anything but perfect hardness is incompatible with indivisibility).

Cor. II. Atoms are perfectly inelastic (since elasticity depends on the amount of motion among smaller particles).

Cor. III. Atoms are impenetrable (since penetrability is intimately connected with softness).

Thus armed, I will attempt to reply to the letters written by Mr. Reynolds. The first argument in Gimel's letter evidently points to the *mathematical* division of an atom, with which we have nothing to do—the atomic theory being a branch of physics and not of mathematics. In the second argument he wishes to know how the parts of atoms are held together; in reply, I direct his attention to corollaries I. and III. As to the last part of his letter I entirely agree with him, not seeing myself the necessity of adopting Dalton's addition. In the first part of his other letter (*i. e.* the one signed A. Reynolds), I think that perhaps there he may be in the right, because, as Richard Laming observes, "the forces of gravitation and cohesion spring from different

sources." However, in the second part of the argument, when he says, "It (*i. e.* an atom) cannot be hard or soft," I refer him again to corollary I. Finally, I have to agree with him that atoms only possess *negative* properties.

I am, &c.

T. S. Barrett.

The Atomic Theory.

To the Editor of the Chemical News.

Sir,—I have not had an opportunity before of replying to the letter of a correspondent in No. 9. of the Chemical News, in which it is endeavoured to be proved that matter is composed of *indivisible atoms*. It appears to me that T. S. Barrett has allowed himself to be misled by his own fallacious argument, and if you will allow me I will point out where I think this fallacy exists. He says that, "if matter were *infinitely* divisible, we should have $r=0$," *i. e.* on the supposition of the *infinite* divisibility of matter, the particles (not atoms) which *compose* matter would be finally lost, in fact, give up their material nature, and become absolute nonentities. Now, it need hardly be said that the objectors to the existence of atoms, do not believe that matter is made up of an infinite number of nothings. And this assumption involves another, *i. e.* that matter is *not* infinitely divisible, for if we suppose that the infinite divisibility of matter results in its destruction, then there is no need to prove that its division cannot be carried further. T. S. B.'s conclusion, without the first assumption becomes worthless; for if, as is undoubtedly the case, r always has some value to whatever extent the division of matter may be carried, the argument drawn from $g \propto r$ merely proves that matter is composed of particles which possess the property of extension.—I am, &c.

J. Noble.

Chemical Nomenclature.

To the Editor of the Chemical News.

Sir,—A correspondent (Your Weekly Guest) asserts that no distinctive title has been applied to the radical NO_6 and others similarly constituted. This I think is incorrect, as in an elementary work on chemistry by Professor Wilson, forming one of the volumes of *Chambers's Educational Course*, it is stated that names have been applied to them; NO_6 is called nitration, SO_4 sulphion, KNO_6 nitrationide of potassium, &c. But I think that any alteration in the existing system would be injudicious, inasmuch as it is supposed to be understood that before a metal can combine with an acid (as NO_6) it must be oxidised; and to be consistent, names must be found for salts containing acids other than those which terminate in *ic*. In addition, there would be the inconvenience of having two systems of nomenclature adopted by those holding opposite views of the nature of acids and salts.—I am, &c.

John Tillman.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

Permanganate of Potash.—Luboldt[1] points out that a standard solution prepared with the crystallised permanganate may be kept a year without any change of composition.

Compounds of Bismuth with Chlorine, &c.—According to Weber[2] protochloride of bismuth is easily obtained by heating the trichloride of bismuth, $BiCl_3$, with metallic bismuth. The protochloride forms a brown black crystalline mass very fusible and decomposable by water. A very high temperature changes it into the perchloride and the metal. Concentrated solution of sal-ammoniac also decomposes it. Analysis leads to the formula $BiCl_2$. It may be obtained by the direct action of chlorine on bismuth, but so conducting the process that the current of chlorine shall only arrive at the upper part of the retort containing the metal. Phosphorus, zinc, tin, mercury, silver, &c. partially reduce the perchloride of bismuth with formation of protochloride. Perbromide of bismuth $BiBr_3$ will also form a protobromide when heated with the metal. It forms a brown crystalline mass presenting analogous characters to those of the protochloride. It has not been obtained in a state of purity: there has always been bismuth in excess.

The tri-iodide of bismuth is easily obtained by projecting small portions of iodine on bismuth strongly heated in a tube, and distilling the product out of contact with the air. It is crystalline and of a metallic black colour. It behaves with bismuth like the tribromide.

II. ORGANIC CHEMISTRY.

The pretended Quinic Ether.—M. Galvani shows[3] that the supposed quinic ether (Chemical News, p. 10) is nothing more than a mixture of ether and alcohol contaminated with some empyreumatic matters; and that the peculiar odour which led it to be considered as a special ether, was due to the presence of some neutral sulphate of methylene.

Saccharide.—After sugar has been melted, a part of it is found incapable of crystallisation and fermentation. To this M. Gelis[4] gives the name of *saccharide*. To isolate it he ferments melted sugar, which destroys the glucose, and leaves the new substance in solution. The solution carefully evaporated gives a syrup, which kept for more than a year in a dry place shows no sign of crystallisation. Saccharide turns the plane of polarisation to the right, but it is changed to the left by the action of acids, or by keeping the saccharide a long time in solution.

Quercitrine in the Coloration of Flowers.—Hlasiwetz[5] suggests that quercetrine may play an important part in the coloration of flowers. He states that one milligramme of quercetic acid is sufficient to communicate a beautiful rose colour to 20 pints of slightly alkaline water. Only a trace of a salt of iron is necessary to colour a solution of quercetine green, and an infinitesimal quantity of quercetic acid will colour blue a very dilute solution of perchloride of iron. With these reactions in view, it is easy to explain the play of colours hyacinths, tulips, and dahlias present, supposing these plants contain quercitrine, which as we have seen (Chemical News, p. 107) contains the elements of quercetic acid and phloroglucine. The concurrence of ammonia, air, or sunlight, and the ferruginous compounds in the sap, will be sufficient to produce the following shades:

Quercitrine or quercetine . . .		colours	yellow
Quercitrine in presence of alkalies and oxygen		„	brown
„ „	sesquioxide of iron	„	green
Quercetic acid		„	blue
„ „	alkalies and oxygen	„	red
Phloroglucine „	sesquioxide of iron	„	violet.

When it is attempted to isolate the colouring matter of flowers but a very small quantity is obtained, which is explicable on the supposition that as only a trace of quercitrine is necessary to give an intense coloration to a solution it may be the same with flowers.

M. Nicklès adds a note in the *Journal de Pharmacie et de Chimie* (Feb. 1860) which says that the above reactions give the key to a sort of industry which has for some years made a great noise in the horticultural world. A pharmacien of Milan has obtained azalias, camellias, &c. of a beautiful blue colour, by growing them in a strongly ferruginous soil. Another amateur has succeeded in the same object by watering his plants with very weak solution of sulphate of iron.

Quercitrine, he adds, is not the only organic matter capable

of these metamorphoses. Salycilic, gallic, pyrogallic acids, and all the varieties of tannin produce with alkalies and salts of iron shades of colour like those of which Hlasiwetz speaks.

III. CHEMICAL ANALYSIS.

Separation of Magnesia from the Alkalies.—M. Chancel[6] applies his method of estimating phosphoric acid (CHEMICAL NEWS, p. 72) for the separation of magnesia from the alkalies. The magnesia is first precipitated in the presence of chloride of ammonium and free ammonia by pure phosphate of ammonia. The proportion of magnesia is thus obtained at once. The filtered liquid and the washings contain the alkalies, ammoniacal salts and the excess of phosphoric acid. It is evaporated to dryness, and the residue is calcined to expel the ammoniacal salts. It is then redissolved in water, and to the solution is added first nitrate of silver, and then a slight excess of carbonate of the same base. If the alkalies are in the state of chlorides, the precipitate with nitrate of silver need not be noticed, for it does not interfere with the action of the carbonate nor with the separation of the phosphoric acid; it is only important to add so much of the nitrate that after the separation of the chlorine enough may remain in the liquid. When the precipitate of phosphate of silver is collected and the liquid is clear and quite neutral, it is filtered, and the excess of silver is removed by means of hydrochloric acid. The alkalies are then in solution quite free from any other fixed principle, and may be determined without trouble by the usual processes.

Detection and Estimation of Iodine.—M. De Luca[7] detects minute quantities of iodine in rain and other waters, by precipitating them with nitrate of silver. The precipitate is washed and thoroughly dried, and is then introduced into a tube in which is also placed a small bottle of very thin glass filled with bromine vapour. The tube is now filled with carbonic acid gas and sealed. It is then shaken to break the bottle and liberate the bromine vapour, which immediately decomposes any iodide of silver, setting free the violet vapours of iodine. These condense in the cold part of the tube and may be dissolved out by alcohol. The amount of iodine may be estimated by a standard solution of sulphurous acid, and the hydriodic acid may afterwards be reconverted into iodide of silver and weighed. The process gives very exact results; as it is conducted in a sealed vessel no loss is experienced.

Lead in Filtering Paper.—M. Wicke[8] calls the attention of toxicologists to the fact that some filtering papers contain lead. A piece four inches square yielded him a distinct precipitate of sulphide of lead.

IV. TECHNICAL CHEMISTRY.

Soluble Glass.—At the request of the Austrian Society of Civil Engineers, Lielegg has studied soluble glass, both with regard to its chemical properties, and its applications.[9] He first examined three specimens of the soluble glass from three different manufactories, and found their composition as follows:

	I.	II.	III.
Water	65·879	38·66	0·689
Silica	22·258	44·64	63·6
Soda	11·178	16·252	„
Potash	„	„	34·4

I. Was silicate of soda made by Siedel of Liesing,
II. Silicate from a manufactory in Munich,
III. Silicate of potash by Kuhlmann of Lille.

The richer the glass is in silica, the less fusible it is. To attain the maximum of fusibility it must contain both soda and potash.

By pouring a concentrated solution of silicate of soda into alcohol, there is formed by degrees a mucous deposit insoluble in alcohol, which hardens after some days. This deposit is soluble in water. The alcoholic mother liquor contains all the impurities in the soluble glass employed. This process of purification is specially applicable to the soluble glass destined to be used in stereochromy.

By triturating soluble glass with quick lime the silicate rapidly hardens, forming silicate of lime and caustic soda. Exposed to the air, the mass becomes covered with an efflorescence of carbonate of soda.

With oxide of zinc soluble glass forms a viscous liquid containing some silicate of zinc, which has already led to the idea of using soluble glass with oxide of zinc in painting.

Combined with hydraulic lime, the silicate forms a good cement for fastening stones: united with fluor spar and powdered glass it becomes like porcelain or marble. Two parts of fluoride of calcium and one part of glass in impalpable powder must be made into a semi-fluid mass, with a solution of soluble glass of 36° Baume. This is applied to the parts which are to be joined, and the pieces are then pressed together until the cement is dry, which will be at the end of some days.

SCIENTIFIC NOTES AND QUERIES.

Utilisation of Spent Bark of Tanneries.—SIR,—In No. 10 of the CHEMICAL NEWS, p. 119, I observe a query as to the "Utilisation of the Spent Bark of Tanneries."

There is one purpose, for which it is extremely well adapted—the manufacture of a gas for heating or illuminating purposes. If the bark is submitted to destructive distillation in a small iron gas retort, the gaseous hydrocarbons, &c. are evolved in considerable quantity, and after being passed through milk of lime can be readily burnt from a jet. The quantity of gas obtained from the bark is so considerable that the expense is a mere trifle. In this condition it is well fitted for a means of heating, but from a deficiency of carbon possesses very slight illuminating power. This defect is easily remedied by passing the gas through naphtha, or some such substance, previous to its combustion, when a gas capable of giving a very brilliant light is procured. On account of the extreme simplicity of the apparatus needful for the production of this gas it appears to be a process in every respect adapted for employment in the country or in private houses.

The destructive distillation of wood for the manufacture of an illuminating gas has, I believe, been employed in some parts of Germany.—*W. Procter, M.R.C.S.*

Bloom on Gutta-percha.—Can any of our correspondents favour us with some information on the subject of the "bloom" which is so often to be seen on the surface of manufactured gutta-percha. A valued correspondent is desirous of investigating its chemical properties, and wishes to know if an ounce or two of the powder can in any way be placed at his disposal.—ED.

LABORATORY MEMORANDA.

Estimation of Mixtures of Acids or Alkalies in Solution.—SIR,—In No. 9, p. 108, of the CHEMICAL NEWS, a method was given for the above purpose. The mode of proceeding was to neutralise a given weight of the mixture of acids with some base, and another portion, of the same weight, with another base, and so on, using as many bases as there are acids in the mixture. It was asserted that there could be obtained by this means as many equations as there were unknown amounts of acid in the mixture. These were to be solved by the usual methods for equations containing more than one unknown quantity. It is necessary for the solution of such equations, that they should be quite distinct, and incapable of being derived from one another; otherwise the equations are in reality the same. In the case before us, having determined the amount of one base required to neutralise the mixture, the amount of any other base necessary for the same purpose is easily calculated. These equations would therefore be useless for the purpose stated.—*A. Reynolds.*

MISCELLANEOUS.

Duty on Chloroform.—Messrs. Smith and Co. of Edinburgh have sent the following letter to the Chancellor of the Exchequer. The subject of it is well worthy the attention of the makers of chloroform. If the duty on French chloroform be remitted, most certainly a drawback should be allowed on the spirit used in its manufacture here.

"Sir,—As manufacturers of chloroform, permit us respectfully to point out to you, that the proposed remission of the import duty on this article, if carried into effect, must extinguish the manufacture of the pure chloroform in this country. A very few words, we think, will prove this:—Pure chloroform requires, as the chief material of preparation, spirits of wine. The cost of spirits of wine 60° O. P. on the Continent and in America, where there is no excise duty on it, is about two shillings and sixpence per imperial gallon; in Great Britain, however, where there is a heavy duty on spirits for revenue, the price is about seventeen shillings per imperial gallon. The great difference between these two prices, in an article *essential* and so *largely necessary* to its manufacture, renders protection not only indispensable, but nothing more than justice to the British manufacturer. It is true, we and others in this country now possess the privilege of using the methylated spirit, but the chloroform from that is used for varnishes, and only medicinally as an outward application, and not by the medical profession for inhalation, for which purpose chloroform is manufactured from pure unmixed spirits of wine. But more than this, as the foreigner can buy pure unmixed spirits of wine cheaper than we in this country can buy methylated spirit, and again, as the yield of chloroform from the latter spirit is less by a good deal, it surely must be plain and undeniable that even the manufacture of this chloroform will also be put down here. The foreign manufacturer will be in a position to introduce into our market (for cost of transit will be more than covered by a less cost for labour) a superior chloroform at a less price than a home manufacturer can offer an inferior one. Should the present import duty on chloroform be abolished, the country that gave birth to the use of chloroform as an anæsthetic, it thus appears, will be in future deprived of its manufacture, and have to draw its supplies from abroad, solely to the advantage of the foreign manufacturer. These remarks could be greatly extended, but, knowing the value of your time, we forbear, confidently trusting that this plain statement of a few facts may prove sufficient for the retention, as originally felt to be, for the imposition of the import duty as an admittedly fair protection, in the circumstances, to the manufacturers of chloroform in our own country."—We are, &c. T. & H. Smith & Co.

The Right Hon. W. E. Gladstone."

The Electric Light applied to Surgery.—One of the greatest obstacles to the success of a surgical operation is the scanty and imperfect light which, in some cases, is the surgeon's only guide, and is fraught with danger to the patient. Thus the extirpation of a naso-pharyngian polypus is almost performed in absolute darkness, it being impossible to bring a common light near enough to the patient without scorching him. The problem, therefore, of finding a light which might be introduced into a cavity with impunity, remained still to be solved; and from a communication sent in a few days back to the Academy of Sciences by MM. Th. Dumoncel, Fonssagrives, and Ruhmkorff, it would appear that this desirable object has at length been attained. Dr. Fonssagrives having long entertained the idea that the electric light might be advantageously applied to the purpose, communicated his views to M. Dumoncel, a distinguished electrician, who calling to mind the effects of electricity *in vacuo*, as exemplified in Geissler's tubes, which although traversed by the electric light reveal no increase of temperature, conceived the following plan for turning this circumstance to account in surgical cases of the nature alluded to. A glass tube, having a very small bore, is bent into the form of a helix or screw (the smaller the bore, the greater is the brilliancy of the light); by this means, a kind of luminous cylinder is formed, which is sufficiently small to be conveniently introduced even into a narrow cavity. Thus the first part of the problem was solved; but the colour of the light was yet to be determined, since this depends on the nature of the gases introduced into the tube. As mixtures of certain gases, such as carburetted hydrogen, carbonic acid, hydrochloric acid, &c. will produce a white light, nothing remained but to fill the tube with such a mixture; and this delicate operation was intrusted to M. Ruhmkorff, who at the same time introduced other valuable improvements into the apparatus. The latter has since been successfully tried in various dental and other operations.

Poisonous Toys.—Very dangerous presents are often made to children. It is the peculiar happiness of juveniles to test, in many homely ways, the strength, flavour, and combustibility of of whatever toys are placed in their hands. The tendency to apply the tongue to all painted toys affords a temptation which only the strongest-minded children can resist; and licking the face of a favourite doll, or the surface of a painted ball, appears to afford pleasure which few can forego. Remembering these infantile idiosyncrasies, kind mammas and generous uncles should endeavour to ascertain that such coloured toys as they give are not painted in mineral colours. Very serious accidents—if we mistake not, deaths—have occurred from licking the aërial bladders which were recently so popular in the nursery. Many of them were painted with arsenical pigments. A sad accident, which occurred this week, at Lyons, points to another favourite toy as a possible source of the most serious misadventure. The "concierge" of the theatre there had presented a box of paints, as a new year's gift, to his son, a boy of about ten years of age. The little fellow was highly delighted with his new acquisition, and passed the whole evening in colouring a large portrait of Garibaldi. Most probably he wetted his pencil or his paints with his tongue; for, in the middle of the night, he was attacked with a violent colic, and died in a few hours, evidently from poison. In the same way the drastic purgative properties of gamboge are not uncommonly developed to a very unpleasant extent. The unfortunate event above described affords an important caution, which will not, we hope, be lost in England.—*Lancet.*

The Administration of Poison.—Sir George Cornewall Lewis and Mr. Clive have introduced a bill into the House of Commons, providing that any person maliciously administering poison with intent to endanger life or inflict grievous bodily harm shall be guilty of felony, and be liable to penal servitude for any period not exceeding ten years, and not less than three years, or to imprisonment for any term not more than three years, with or without hard labour at the discretion of the court. Any person maliciously administering poison with intent to injure, aggrieve, or annoy any other person, will be guilty of a misdemeanour, and liable to imprisonment not exceeding three years, with or without hard labour at the discretion of the court. The costs and expenses of the prosecution of any such misdemeanour may be allowed by the court as in cases of felony. If, upon the trial of any person charged with the felony, the jury shall not be satisfied that such person is guilty thereof, but that he is guilty of the misdemeanour, then the delinquent will be liable to be punished in the same manner as if convicted upon an indictment for the misdemeanour.

The Administration of Poison Bill was read a third time, and passed the House of Commons on Wednesday last.

The Adulteration of Food Bill was in Committee on Wednesday, and the three first clauses were agreed to.

ANSWERS TO CORRESPONDENTS.

*** In publishing letters from our correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

Messrs. Silliman and Dana's courteous request shall be attended to immediately.

H. K. B.—Addresses are given in confidence. We shall be happy to forward a communication to *W. G. P.*

W. H. (Tillydesk)—Our correspondent has misunderstood us. We did not intend to republish the article in question. The process is only available for the separation of phosphoric acid in one condition.

W. J. J.—1, Copal and anime varnishes are made with spirits of wine, and the copal is burned for a few seconds, which makes it more soluble. A mixture of sandarac and mastic is said to increase the solubility of copal. 2, Nothing better than soap and water, and sometimes a little alkali.

A. W. P.—For the oxyhydrogen lime-light see page 152. The Fitzmaurice light soon.

L. Greg.—The arsenic sold is *arsenious acid.* A very few grains are sufficient to poison a man. We hope our correspondent has no evil intentions.

W. Sale—We believe the book was published by Messrs. Chambers of Edinburgh. The same information will be found in most works on chemistry.

E. H. (York)—The tannate of alumina is prepared in the same way as the tannate of bismuth. (See p. 137.) Rub together equivalent proportions of freshly precipitated alumina and tannic acid.

A. B.—Make them hot.

P. H. Hemschikoff—received.

Mr. Salter—received with thanks.

*** All *Editorial Communications* are to be addressed to the Editor; and *Advertisements* and *Business* communications to the Publisher, at the Office; 12 and 13 Red Lion Court, Fleet Street, London. E. C.

THE CHEMICAL NEWS.

Vol. I. No. 14. — March 10, 1860.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Researches on the Organo-metallic Radicals, by M. Auguste Cahours.

(*Concluded from* p. 147.)

Oxide of Stannethyl. — When an alcoholic solution of iodide of stannethyl is poured into a solution of ammonia diluted with an equal volume of alcohol, oxide of stannethyl separates as a gelatinous mass. An excess of ammonia and caustic potash redissolve it. In order to obtain it perfectly pure the gelatinous mass is thrown on a filter and washed successively with hot water and boiling alcohol, until the washings no longer contain either the iodide or ammonia. The product is then dried first on water bath and then in vacuo. So prepared oxide of stannethyl is an amorphous white powder, insoluble in hot and cold water, alcohol and ether. It dissolves easily in hydrochloric, hydrobromic, hydrofluoric and hydriodic acids; and these solutions by spontaneous evaporation deposit beautiful prismatic colourless and odourless crystals of the chloride, bromide and iodide and fluoride of stannethyl.

Boiling acetic and formic acids give with oxide of stannethyl viscous products, which on cooling form a crystalline mass. These substances dissolve in hot alcohol, and by evaporation separate in the form of colourless tables. Butyric and valeric acids behave in a similar way.

A dilute and boiling solution of tartaric or citric acid dissolves oxide of stannethyl, and on cooling deposits small prisms of tartrate and citrate of stannethyl. Oxalic acid forms an insoluble compound with oxide of stannethyl.

Nitric and sulphuric acids, especially when hot, dissolve the oxide easily, and the evaporation of the solutions gives crystallised products.

Dilute solutions of potash, soda and caustic ammonia do not dissolve oxide of stannethyl, nor do they decompose it. When however the oxide is distilled with an excess of caustic potash, it is split up into a very volatile product, which may be condensed at a very low temperature in the form of beautiful colourless prisms, having a powerful odour and a strongly alkaline reaction on reddened litmus paper. This is the oxide of sesquistannethyl: there is formed beside some stannate of potash. The reaction is easily explained by the following equation:

$$3(SnC_4H_5O) + KO = SnO_2KO + Sn_3(C_4H_5)_3O.$$

Perchloride of phosphorus with the aid of a little heat quickly attacks the oxide of stannethyl. On distillation a fuming liquid may be condensed in a well-cooled receiver, from which thin crystals deposit. Water decomposes the liquid part, which is oxichloride of phosphorus, but does not attack the crystals. These may be purified by repeated washings with cold water, pressing between folds of filtering paper, and recrystallisation from alcohol, and then present the properties and composition of chloride of stannethyl. The preceding reaction may be explained by the following equation:

$$2(C_4H_5Sn\,O) + PCl_5 = PCl_3O_2 + 2(C_4H_5SnCl).$$

All the salts formed by stannethyl when they are soluble crystallise with facility. Heat decomposes them either partially or completely. In all the distillations the same acrid odour is observed, like that of essence of mustard, which characterises sesquistannethyl and its various combinations.

Sesquistannethyl Series. — We have seen that by the action of iodide of ethyl on tin there is formed besides the solid and crystallisable iodide an oil with a powerful acrid odour, a larger proportion of which is obtained when an alloy of tin and sodium is used in the place of pure tin.

When purified by rectification the oil (which is the iodide of sesquistannethyl) possesses the following properties. It is a heavy liquid, either colourless or of a pale amber. It boils without undergoing the least alteration between 235° and 238°. Its density is 1·833 at 22°. It is easily soluble in alcohol and ether, and only slightly soluble in water.

When cold it dissolves iodine without change, but when heated the iodine disappears. By continuing the addition of iodine, the solution soon ceases to be decolorised, and there is formed an etherial liquid which boils under 100°, and which has all the properties of hydriodic ether. On cooling the liquid becomes a mass of crystals which may be purified by pressing between folds of blotting paper and crystallisation in alcohol. In this way we obtain beautiful colourless prisms which are no other than the iodide of stannethyl.

Oxide of Sesquistannethyl. — An aqueous solution of caustic potash decomposes iodide of sesquistannethyl with the formation of iodide of potassium and oxide of sesquistannethyl, which dissolves in an excess of the alkali. When distilled this mixture yields oxide of sesquistannethyl and water. The aqueous solution serves for the preparation of the salts: the mass which solidifies on cooling the receivers may be purified by pressing in blotting paper and fresh distillations. So purified the product presents itself in the form of brilliant colourless prisms, which fuse between 44° and 45°, and distil at 272°. Water, alcohol, wood spirit, acetone and ether dissolve it easily. If kept for some time at a temperature near its boiling point water is disengaged, and the anhydrous oxide is obtained in the form of a limpid oil. The crystals then are an hydrate, which is proved by allowing water to fall drop by drop on the oily matter.

The aqueous solution has strongly alkaline reactions; it turns the syrup of violets green, restores the blue of reddened litmus paper, and saturates the strongest acid. When hydrochloric acid is brought near the oxide in a state of fusion, thick fumes are produced.

The salts formed by the oxide are nearly all soluble, and crystallise with the greatest facility: all have a strong acrid odour. The chloride, bromide and iodide of

sesquistannethyl are liquid, and have a strong acrid smell which resembles that of mustard.

The composition of oxide of sesquistannethyl is expressed by the formula:

$$Sn_2(C_4H_5)_3O.HO.$$

Action of Tin on Iodide of Methyl. Stanmethyla.—The iodide of methyl in contact with tin or an alloy of tin and sodium furnishes results exactly corresponding to those obtained with the iodide of ethyl.

When the iodide of methyl is heated with pure tin in a sealed tube to between 150° and 160°, the metal disappears in about 12 or 15 hours, if 3 parts of the iodide are used to 1 of tin. On cooling the tube a brown liquid is obtained which sometimes deposits magnificent crystals of a sulphur-yellow colour. Submitted to fractional distillation the liquid begins to boil about 50°, when a small quantity of unchanged iodide of methyl passes: the temperature then rises gradually, and the last portion passes over towards 230°. The greater part of the product distils between 180° and 230°. The residue left in the retort is red iodide of tin. The rough product of this first distillation deposits on standing a considerable quantity of the sulphur-yellow crystals mentioned above. The supernatant liquid from the crystals submitted to a new rectification begins to boil at 180°, and the distillation is finished at 230°. Towards the middle of the distillation the liquid becomes turbid and the red iodide of tin is separated. The product of this second distillation still deposits after some hours rhombohedral crystals. The liquid is separated from these and submitted to a third rectification, care being taken to collect what passes above 200° in a separate receiver. From this a considerable quantity of yellow crystals is deposited. To purify these the different deposits are collected together and pressed between blotting paper until they cease to stain it. A saturated solution of them in a mixture of alcohol and ether is then made, filtered, and allowed to evaporate spontaneously over strong sulphuric acid under a bell glass. The evaporation should be carried on in the dark, or the crystals will be of a brown colour. In this way we obtain oblique rhomboidal prisms of considerable size and perfect clearness, but which become opalescent in the air. They melt at about 30° into a liquid having the appearance of melted sulphur, which by slowly cooling becomes a mass of beautiful rhomboidal prisms. The product has a constant boiling point of 228°. Its density at 22° is 2·872. The crystals dissolve in water, especially when warm, alcohol, and wood spirit; acetone and ether dissolve them in considerable quantity. The alcoholic solution is decomposed by the sulphate, nitrate, acetate, &c. of silver, with the formation of iodide of silver, and the corresponding salts of the oxide of stanmethyl.

Ammonia decomposes a solution of these crystals, and gives a white amorphous precipitate of oxide of stanmethyl, insoluble in an excess of the precipitant, and presenting the greatest resemblance to the oxide of stannethyl. On analysis results were obtained which conducted to the formula: C_2H_3SnI.

2C	12		5·97
3H	3		1·49
Sn	59		29·35
I	127		63·19
	201		100·00

The crystallised compound is therefore the iodide of stanmethyl, homologous with the iodide of stannethyl formed under similar circumstances. The product boiling between 180° and 200°, rectified several times until it no longer deposited the red iodide of tin, yielded finally a colourless, limpid, very mobile liquid, possessing an acrid odour resembling that of mustard, but less penetrating than the smell of the iodide of sesquistannethyl. It remained liquid in a mixture of ice and salt, but solidified immediately in a bath of solid carbonic acid and ether. Its density at 18° is 2·155: it boils between 188° and 190°. It is but slightly soluble in water, but dissolves in all proportions in alcohol and ether. Potash decomposes it, forming iodide of potassium and a corresponding oxide, which is soluble in an excess of the alkali. When this solution is distilled, vapour of water passes over, carrying with it some of the oxide, which may be condensed in a cooled receiver. It is a colourless oil with a very strong smell, which at a low temperature becomes solid in the form of prisms of remarkable beauty. When analysed results were obtained which agree with the formula $Sn_2(C_2H_3)_3I = Sn_2C_6H_9.I$. In its composition and properties this compound exactly corresponds to the iodide of sesquistannethyl.

Oxide of Stanmethyl.—This compound is obtained by decomposing a solution of the iodide of stanmethyl with an excess of ammonia, throwing the precipitate on a filter, washing with very dilute alcohol, and then with pure water, until there is no longer a precipitate with nitrate of silver. The product carefully dried forms an amorphous white powder, tastless, insoluble in water, alcohol, ether, and alkaline solutions. Heat decomposes it, giving off a strong penetrating odour, due to the formation of oxide of sesquistanmethyl. By distillation with an excess of caustic potash, it is also decomposed, like its homologue the oxide of stannethyl, the oxide of sesquistanmethyl passing over with the water, and stannate of potash remaining in the retort. This reaction is explained by the following equation:

$$3(C_2H_3SnO) + KO = SnO_2.KO + Sn_2(C_2H_3)_3O.$$

Hydrochloric, hydrobromic, and hydriodic acids easily dissolve the oxide of stanmethyl, and the solutions evaporated give perfectly defined crystals. Sulphuric, nitric, formic, acetic, butyric acids, &c. form with it compounds which crystallise in a remarkable manner; the sulphate in particular furnishes large crystals of great beauty.

The salts formed by the oxide of sesquistanmethyl are nearly all soluble, crystallise easily, are volatilised without undergoing alteration, and have a strong smell like that of the iodide. They are isomorphous with those formed with the oxide of sesquistannethyl.

From the preceding history of the stannethyls and methyls, it is seen that tin forms with methyl and ethyl three definite compounds:

SnE	$SnMe$
Sn_2E_3	Sn_2Me_3
SnE_2	$SnMe_2$

which correspond with the oxides of tin

$$SnOSn_2O_3SnO_2$$

The two first terms of the series can fix oxygen, chlorine, iodine, &c. to form compounds like those which tin itself forms, and may be separated intact from these combinations, thus behaving exactly like a simple body as long as the equilibrium of their molecule is not affected. The last term of each series, *distannethyl* and *distanmethyl*, cannot unite with oxygen, chlorine, or their analogues, inasmuch as this term represents the limit of saturation for the combinations of tin. If submitted to the action of these bodies, they lose methly or

ethyl, (which is disengaged in the form of oxide or chloride) at the same time passing to the state of mono- or sesqui-stannethyl, &c. substances which not having attained the limit of saturation, can contract alliances with chlorine, iodine, bromine, &c. and so produce the compounds we have studied.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY, 1 *March* 1860.

DR. A. W. MILLER, *in the Chair.*

MR. RILEY read a paper *On the New Zealand Iron Sand.* The New Zealand Iron Sand, from its fine state of division and richness, induced the author to make use of it for some experiments on the reduction of iron ores with various matters; and as titanic acid had not been tested for in the analysis published (CHEMICAL NEWS, p. 116), it was thought necessary to see whether it was present. 60·25 grains of the finely powdered mineral were therefore treated with hydrochloric acid, containing a little nitric; although it was boiled for some time, complete solution of the iron could not be effected (this was afterwards found to be due to the ore not being sufficiently pulverised, as it was found to be completely soluble in a very short time in strong hydrochloric acid, if in an impalpable powder). The solution was diluted with water and allowed to stand all night; it did not get clear, and great difficulty was experienced in filtering it. The filtrate evaporated to dryness left a residue upon redissolving in hydrochloric acid, of 3·71 grains, slightly coloured with peroxide of iron. This was fused with bisulphate of potash, treated with cold water and slightly warmed; complete solution could not however be effected without the addition of some sulphuric acid. On boiling a considerable precipitate was obtained; the whole of the titanic acid could not be completely thrown down unless some of the large excess of acid was neutralised (still leaving however the solution very distinctly acid), the precipitate, on testing with microcosmic salt, gave the distinct reaction of titanic acid. The residue insoluble in HCl was tested for titanic acid, and found to contain a considerable quantity. The sample employed in some of these experiments is the same that was analysed and the results given in CHEMICAL NEWS, p. 116.

I. 18·08 grains of ore dissolved in nitro-hydrochloric acid gave a residue of 1·17 grains. The filtrate, evaporated to dryness and heated, gave a residue on resolution in hydrochloric acid of ·60, which was slightly coloured with peroxide of iron. The filtrate from the latter, evaporated to dryness and re-dissolved, still gave a residue of titanic acid. Two other trials were made to see if titanic acid could be separated by evaporating to dryness; the results were however most unsatisfactory, and the method was therefore abandoned.

Two portions of ore were weighed out and dissolved in hydrochloric acid.

I.	18·08	gave 1·17	residue insol. in HCl	=	6·47 per cent.
II.	19·31	„ 1·24	„ „	=	6·42 „
III.	19·83	„ 2·41	„ „	=	12·15 „

Portion No. II. was not submitted to the action for more than 20 to 30 minutes: complete solution was effected in that time.

No. III. was heated for one or one and a half hours on th sand bath, until about half the original quantity of acid had been evaporated off. Some of the titanic acid was evidently separated and became insoluble by this method.

Residue II. was fused with bisulphate of potash, dissolved in warm water, and some sulphuric acid added. All the titanic acid appeared to dissolve, leaving a siliceous residue, which was filtered off: it weighed ·87; treated with hydrofluoric acid and sulphuric acid ·48; difference equal silica, ·39.

No. III. residue treated with hydrofluoric acid and sulphuric acid, gave a residue of 1·88.

Percentage of silica in	No. I.	.	.	.	2·02
„	No. II.	.	.	.	2·67

The above sample was not the same as that analysed, the results of which were given in CHEMICAL NEWS, p. 116.

An experiment was made on a solution of titanic acid in bisulphate of potash to see whether it behaved similarly to peroxide of iron and alumina with acetate of soda. It was found that titanic acid was completely separated by boiling with acetate of soda, no precipitate being produced on testing the filtrate with ammonia. The solution of No. II. was therefore treated as in the analysis of iron ores, viz. acetate of soda was added, and it was then boiled; no difficulty was experienced in washing, and the separation of the titanic acid was complete; no precipitate being produced in the filtrate by ammonia. The basic peracetate of iron, &c. was dissolved in HCl, and precipitated by ammonia and weighed. The weight obtained was 18·81 grains. The filtrate from the precipitate by ammonia gave no precipitate on evaporating nearly to dryness. The 18·81 grains treated with hydrochloric acid left a brown powdery residue, which by long boiling appeared to dissolve to some extent, and was evidently titanic acid coloured with iron. This had not been examined further.

Upon determining the iron direct by means of a standard solution of bichromate of potash, the mean of two determinations for obtaining the value of the standard solution showed that 1000 grains by measure of the solution = 4·996 grains of iron.

In the iron ore:

				Per cent. of iron.
A.	18·60 grains required	2120 measures of the solution	=	56·94
B.	19·63 „	2244 „	„	= 57·11

Giving a mean result of 57·03 per cent. of iron.

In two other determinations, viz. in (A′.) iron sand from Mr. Ridgway, Leicester Square; (B′.) iron sand from a friend in Monmouthshire:

				Per cent. of iron.
A′.	18·26 grains required	2116 measures of the solution	=	58·99
B′.	20·59 „	2367 „	„	= 57·43

The amount of titanic acid, alumina, and phosphoric acid may be determined thus:

Iron Sand.	Iron.	Iron Sand. Portion II.	Iron.
100	: 57·03	:: 19·31	: 11·01.

∴ Portion II. gave by calculation from A and B results,

11·01 Fe = 15·73 Fe_2O_3

Portion II. gave,

18·81 Fe_2O_3, TiO_2, AlO_3, and PO_5 (if present).

∴ 18·81 − 15·73 = 3·08

3·08 being chiefly, I believe, TiO_2.

The percentage of protoxide of iron is in excess of that requisite to form Fe_3O_4. Thus:

18·6 of ore gave 773 measures same stand. = 26·69. per cent. of FeO.

The ore was dissolved in a flask in an atmosphere of carbonic acid and filled up with cold boiled distilled water, the FeO then determined by standard solution.

Mr. Riley intended to present to the Society a complete analysis; circumstances however prevented this, and he trusted the necessity of correcting an error would be a sufficient apology for presenting such imperfect results.

DR. GLADSTONE said that in the analysis given in the short mineralogical paper referred to above, he had simply followed the course usually adopted in such cases, and thus had overlooked the presence of titanic acid. Dr. Noad had since pointed out to him the fact that some samples of New Zealand iron sand contained that substance; whereupon of course he saw the necessity of repeating the analysis, and of withdrawing his communication if his sample was found to contain titanic acid. He had not been able to turn to the matter till the previous day; but on a somewhat hasty

analysis of his specimen, he had succeeded in finding a trace of titanic acid in the insoluble portion, and just one per cent. in the soluble portion—not the larger amount mentioned that evening. He confirmed the observations on the difficulties attending the examination of ilmenite, and the estimation of titanium, and pointed out several directly contradictory statements in works of standard reputation as to the solubility and other properties of titanic acid. He hoped Mr. Riley would be able to reconcile these, and to induce chemists to search for this substance in places where it was not now suspected. The paper was accordingly withdrawn.

Dr. Hofmann then made a verbal communication, an abstract of which we hope to give next week.

At the last meeting of the council of the above Society, the following arrangements for future evenings were decided upon:

On Thursday, April 5, Dr. Thomas Andrews, M.D. F.R.S. M.R.I.A. will deliver a discourse *On Ozone.*

On Thursday, May 3, Dr. J. H. Gladstone, Ph.D. F.R.S. will deliver a discourse *On Circular Polarisation.*

On Thursday, June 7, Dr. Frankland, F.R.S. will deliver a discourse *On Organo-Metallic Bodies.*

In addition to the above, the Society will meet as usual on the evenings of March 15, April 19, May 17, and June 21. Whenever practicable, the titles of the papers to be read or the subjects of discussion at any of the meetings will be previously announced in the Chemical News.

The next meeting will be held on March 15, when there will be a paper read on the *Platinid-cyanides* by Mr. Hadow, and on a new *Ammonio-chrome compound.*

PHARMACEUTICAL SOCIETY, 7 *March* 1860.

T. N. R. Morson, *Esq. President, in the Chair.*

The following papers were read, which, by the courtesy of the authors, we are able to give at greater length than usual.

On Syrupus Ferri-phosphatis, by Mr. Schweitzer.

The several difficulties experienced in obtaining this syrup according to the formula given by Mr. Greenish in the *Pharmaceutical Journal*, vol. xii. p. 311, the vagueness of this form and some peculiar properties of the phosphates of iron induced the writer to try a series of experiments, the result of which he is induced to publish.

Before entering into a discussion on this subject, it may be as well to point out those objections which the syrup usually offers.

1. The syrup is either too acid; or
2. The phosphate of iron is from the commencement in an insoluble condition;
3. The syrup is bright at first, but soon becomes turbid;
4. Or the permanent solubility of the phosphate of iron is due to the presence of a foreign salt.

In dissolving the dry perphosphate of iron such as Mr. Greenish's form would lead us to select, we find that a very strong, usually glacial phosphoric acid is required for effecting its solution; and that heat instead of assisting, either prevents the solution, or precipitates the dissolved phosphate of iron. In mixing, moreover, such a cold prepared strongly acid solution with the requisite amount of simple syrup, the result will still be very acid, and if bright at first, soon becomes cloudy and throws down part of its iron. The addition of dilute sulphuric or hydrochloric acid, or a citrate of ammonia, soda or potash, delays and even prevents the precipitation of the phosphate of iron; but as such an addition has always to bear a certain proportion to the amount of iron and excess of phosphoric acid in the syrup, this becomes objectionable, especially as we may arrive at the same result without it.

After various trials it was found that fresh precipitated moist phosphate of the protoxide of iron gave the most satisfactory results, and at the same time led the writer to suggest a new, and as he hopes, more definite and explicit mode of making the *Syrupus Ferri-phosphatis.*

A solution of the tribasic phosphate of the protoxide of iron is selected as the base of the syrup, which is made according to the following form. Take of

Sulphate of iron in crystals	℥iij
Phosphate of soda	℥iij
Carbonate of soda	℥ss
Water	℥ss
Phosphoric acid, Ph. L.	fl℥xxj

The phosphate and carbonate of soda are pounded together in a mortar, and when fine the sulphate of iron is added and the trituration continued, gradually adding the ℥jss. of water till a uniform fine blue mass is produced. This when well washed is thrown on a filter, drained, and while moist introduced into a glass measure; it should occupy rather less than 6 fluid ounces, and if less the deficiency should be made up with distilled water. These 6 ounces of fresh precipitate are mixed and dissolved in 21 fluid ounces of dilute phosphoric acid of Ph. L. and the resulting solution filtered and kept for use.

Five fluid ounces of this solution when mixed with 9 fluid ounces of simple syrup, produces a *syrupus ferri-phosphatis* containing 1 grain of phosphate of iron and about 16 minims dilute phosphoric acid in a fluid dram. The above amount of iron is considerably larger than that actually found in Mr. Greenish's syrup.

The formation of the phosphate of iron, its subsequent washing and solution in phosphoric acid, and the addition of syrup to the solution — all these operations have to be effected without the application of heat.

The above form for the preparation of the phosphate of iron with the addition of carbonate of soda is recommended, because the amount of phosphoric acid contained in a certain quantity of phosphate of soda is more than sufficient to combine with the iron contained in an equal quantity of of sulphate of iron: and as the soda in the phosphate is not enough to neutralise the liberated sulphuric acid, the excess of which (with the free acid always contained in commercial sulphate of iron), would cause the solution of and subsequent loss of a considerable amount of the freshly precipitated phosphate, the carbonate of soda is added, which will entirely prevent the loss.

On Syrup of Superphosphate of Iron and other Phosphates used in Medicine, by Mr. Samuel Gale, *F.C.S.*

(This paper will be given in our next number).

On the Preparation of Pyrophosphate of Iron by Mr. J. Robbins.

Among all the elementary bodies not one gives so large a number of beautiful and interesting preparations employed as remedial agents as iron; and were it not that the medical man has already so large a number at his command that he is somewhat perplexed in making his selection, the number might be increased almost *ad infinitum.* One of the most recently introduced curative agents is the so-called pyrophosphate of iron, a salt more beautiful in appearance than the ammonio-citrate or any other of the scaled salts previously in use. Its colour varies according to the mode of manufacture. It may be made of a greenish or decided green colour, or yellow, or even of a reddish tint. Water dissolves it readily. Its taste has little to indicate its ferruginous character, but is rather that of a pleasant saline, agreeable to the most fastidious palate.

The name given to the salt is decidedly objectionable. The science of chemistry within the last few years has made such rapid progress that there is scarcely a day but some new compound is announced to the scientific world, some with such long and formidable names that it requires more

courage than many possess to attempt even to pronounce them, while few memories can command them at pleasure. I think it therefore a pity when a new preparation is introduced of rather an indefinite composition that the difficulties already existing should be increased by giving it the name of a definite chemical compound well known. The salt in question physically bears no relation to pyrophosphate of iron, and all that can be said chemically is that this compound is one of its constituents.

Pyrophosphate or bibasic phosphate of iron is obtained by adding a solution of persulphate or perchloride of iron to a solution of bibasic or pyrophosphate of soda. It forms a white precipitate, quite insoluble in water and dilute acids. The pyrophosphate of soda is obtained by simply igniting to redness in a crucible the tribasic or ordinary phosphate of soda. The two phosphates of soda are best distinguished by nitrate of silver, which gives with the pyrophosphate a white, and with the ordinary phosphate a yellow precipitate. Recently precipitated pyrophosphate of iron obtained as above is readily dissolved by pyrophosphate of soda, and by the citrates of potash, soda, and ammonia. When pyrophosphate of soda is used as the solvent, and the solution is allowed to evaporate spontaneously in a warm place, a nice looking transparent salt is obtained, which however is nearly insoluble in water, evidently from some change having taken place during desiccation. The citrates of soda, potash and ammonia freely dissolve the pyrophosphate of iron, yielding salts readily soluble in water; but the soda citrate I find to give the most satisfactory results. With it an elegant preparation may be made, which is easily scaled, readily dissolved by water, and which when exposed to the air retains its brilliancy a much longer time than if prepared with the citrate of potash or ammonia.

To prepare this salt — the best name for which would be *citro-pyrophosphate of iron* — take citrate of soda dissolved in a small quantity of water, and with the assistance of heat dissolve in it as much of the recently precipitated pyrophosphate of iron as it will take up. Filter the solution, and evaporate to the consistence of a syrup. Lastly, spread on glass plates to dry, when beautiful scales of a greenish-yellow colour will be obtained. One part of dry citrate of soda is required to dissolve the pyrophosphate precipitated from one part of the pyrophosphate of soda free from water of crystallisation.

As it may be considered desirable to introduce as much bibasic phosphoric acid as possible into this preparation, the following formula may be preferred:—

Take of pyrophosphate of soda . .	1 part,
„ syrupy citrate of ammonia . .	1 part,
„ citrate of soda	2 parts.

Dissolve in them as much of the recently precipitated pyrophosphate of iron as possible, and proceed as before. The salt formed by this process is also a very elegant one, having a greenish hue, and being perfectly soluble. If a reddish tint be desired, it can be easily obtained by the addition of the smallest quantity of ammonio-citrate of iron to the syrupy solution. One of the chief points of success in scaling this preparation is to take care that the glass plates are not subjected to a temperature much above summer heat.

The Chairman said that the papers which had been read were valuable contributions, although they contained nothing which could be said to be new. The syrup of the phosphate or superphosphate of iron, for it was sometimes called by one and sometimes by the other name, though strictly speaking it was a superphosphate, had long been prepared by dissolving freshly precipitated phosphate of iron in a clear syrupy phosphoric acid. The pyrophosphate was an elegant, tasteless, and valuable medicine, well worthy of attention. He thought it a pity that the compound syrups had been introduced. The meeting would be happy to hear any remarks from gentlemen practically acquainted with the making of these preparations.

Dr. Redwood made some remarks on the importance of uniformity in the preparations.

Mr. Waugh said that the syrup with nickel was largely used by Dr. Simpson in Edinburgh, and inquired of Mr. McFarlane for some information respecting it.

Mr. McFarlane said he came to London to learn.

Mr. Cook and Mr. D. Hanbury, Jun. gave an account of some articles called Pulu, Penawar-jambi, and other longer names. They all consist of the shiny hairs which grow on the rhizomes, and stems of various ferns found in the Sandwich Islands, in Batavia, Java, and Madeira. Pulu, the article from the Sandwich Islands, had become an important article of commerce. The quantity exported from the islands in 1851 was only 2000 lbs.; in 1858 it had increased to 213,000 lbs. The quantity obtained from one fern was only 2 or 3 oz., and the time necessary for the growth of this was four years. It was principally exported to San Francisco, where it was used for stuffing pillows and cushions. The ferns from which it is obtained are found on the highlands at an elevation of 2000 to 4000 feet, and they sometimes grow to the height of 15 feet. The article from Java had been introduced into medicine as a styptic.

Dr. Redwood then made an important communication on the subject of Hydrargyrum cum Cretâ, which the great length to which our report extends obliges us to defer until next week.

SOCIETY OF ARTS, 29 *Feb.* 1860.

George Godwin, *Esq. F.R.S. in the Chair.*

The attention of the meeting on this occasion, was devoted to a paper by Mr. G. R. Burnell, *On Building Stones*, the causes of, and means of preventing, their decay being especially considered. Mr. Burnell's communication was a very lengthy one, but we will endeavour to lay his views before our readers in a condensed form. In the first place, attention was drawn to the influence of local material upon the architecture of towns, the general style of London, and other places where bricks are almost entirely employed, being contrasted with that of Edinburgh, Bradford, Paris, &c., where stone is cheap and abundant. A general classification of the building stones used in the metropolis followed, and the distinctive characters of the freestones, and of those requiring picks and wedges to work them, were severally pointed out. The chief sources of granite and its allies were thus enumerated:

"The London market consumes large quantities of granite from the Channel Islands, Cornwall and Devonshire, Mount Sorel in Leicestershire, Aberdeen and Peterhead in Scotland. The whinstones, basalts, and volcanic tufas, are hardly ever seen here — unless in the form of the pozzuolanos and trap, which are occasionally imported from Italy and Germany for making artificial hydraulic cements — whilst the quartz rocks and the quartzose sandstones, the mica schists, &c. are never used. The quartzose conglomerates, such as the Bramley Fall stone, are occasionally employed in engineering works, and the tertiary grès, or sandstones, of Windsor forest are used in the neighbourhood of Windsor as paving materials for streets and stables, just as the grès of Fontainebleau, their geological analogues, are used in Paris."

The Lecturer said that the advantages of this class of materials consists in their great hardness, density, and impermeable nature, while the objections to their use are the cost of working, which is very high, and the heterogeneous composition they generally exhibit,—a fruitful source of decay. Speaking of the cause of such disintegration, he observed, "the Cornish and the Devonshire granites, and some of the porphyries and elvans from those counties, frequently contain a notable proportion of felspar; and when they are exposed to the action of rain-water, containing (as it usually does) carbonic acid in solution, that felspar decomposes, and is then easily removed, leaving the quartz and the mica in relief

without any cementing material. Illustrations of this mode of decay may be observed in the granite used in parts of Waterloo or London Bridges, or in the granite piers of the crypt under the hall of Christ's Hospital; but the process is very slow, and it would seem to be subject to some laws not hitherto discovered, for the decay of the felspar does not take place according to any known rules. The more crystalline, in fact, the felspar of any of these bodies may be, the more perfectly does it resist the decomposing action of the atmospheric agents; and we shall have occasion again to allude to the influence of this mechanical state of natural substances upon their durability. In the meantime it may be added, that in the Bramley Fall and in the analogous stones, the siliceous conglomerates, the same phenomena may be observed. The cementing material frequently decomposes, and is washed away from the ingredients it naturally held together, and then the latter as certainly fall asunder, or the cementing material decays, and in so doing it produces a dangerous disintegration of the mass. It follows from these observations that the smaller and the more uniform in dimensions the materials of these heterogeneous rocks may be, the greater is the probability of their duration, and in the case of granite especially it is essential to select those descriptions which do not contain large crystals of felspar. It is singular that some of the granites of Normandy, Brittany, and the north of Spain, present identically the same mineralogical peculiarities as the granites of Devon and Cornwall, and they are equally susceptible of decay. The varieties in the lithological characteristics of the Bramley Fall stone, and in those of the quartzose conglomerates are still more hard to define than even those of the plutonic rocks; in the same quarry, and even in the same bed, the qualities of these stones will change within a very small distance, and the great irregularities of this description of stone form in fact the most serious objection to its use. Nevertheless when the Bramley Fall or the siliceous conglomerates are well selected, they are extremely valuable for engineering purposes, on account of their hardness and of their power of resisting crushing weights. They yield to atmospheric influence when the siliceous cement exists as soluble silica, and is of an amorphous character; if on the contrary the cement assume a crystalline character, it becomes unattackable even by caustic alkaline solutions, and the siliceous conglomerates are then as durable as the best descriptions of granite themselves. Of the granites which are used in London, those obtained from Aberdeen, Peterhead, and Mount Sorel are the most valuable, but also, on account of their hardness, the most expensive."

Turning to the freestones most commonly used in London, the list runs thus:—"Amongst the sandstones, the Craigleith, the Dundee and Arbroath, the Yorkshire stones, and the sandstones furnished by the Wealden deposits near Tonbridge Wells, or by the subcretaceous formations of the neighbourhood of Godstone, Maidstone, or Folkestone; amongst the magnesian limestones, the Anston and Bolsover stones; amongst the carbonates of lime, the Portland, Purbeck, Ketton, Barnac, the Caen, Ranville, Aubigny stones, are to be met with in commerce without difficulty, whilst it would be easy to increase their number by the introduction of the remarkably valuable tertiary limestones of the Paris basin. In some localities even the common chalk becomes so indurated as to allow of its being used as a building stone; less frequently, it is true, in England than in France, for in the valley of the Lower Seine this material is extensively used in the best buildings, as at Rouen, Vernon, Louviers, &c." The sulphates of lime ("gypsum," "selenite," &c.) were then noticed as sources of "plaster of Paris," &c. as also were the various argillaceous limestones from which we obtain the "Roman" and "hydraulic" cements. Sandstones came next, but we shall content ourselves with a few figures merely from this part of the paper. The Craigleith stone, used largely in Edinburgh, is "composed of minute grains of quartz, with occasional plates of mica, united by a siliceous cement, containing usually about 98 per cent. of silica, 1 of carbonate of lime, and 1 of bitumenous and other miscellaneous ingredients. The weight of a foot cube of the Craigleith stone is about 146 lbs. and it is stated to resist a crushing weight of 5800 lbs. on the inch superficial." The Dundee and Arbroath stones offer no points of special interest; but the Yorkshire sandstones, with which London is paved, demand our attention for a moment. Here we note that their strength and density about equals that of the Craigleith; that although freely permeable to water frost has but little destructive action upon them in general, owing to the distinct and regular lamination, but that, nevertheless, they do not "stand well between wind and water," as when placed in basements or plinths of buildings. As instances of the diversity of results obtained with magnesian limestones, from the Anston and Bolsover quarries, the Museum of Practical Geology on the one hand, and the Lincoln's-Inn Library and new Houses of Parliament on the other, would be familiar to all. The oolites are far too important to be neglected, for ranged in this series we find the Barnack, Ketton, Ancaster, Portland, Bath, Caen, and other stones, with whose leading characteristics we are most of us acquainted. The Barnack, or more properly, the Casterton stone, for the original Barnack quarries have been long abandoned, is of a light-brown tint, its density being 2·09, while the weight required to crush it, is not more than one fourth of that demanded by the Craigleith stone. When carefully selected, the Barnack oolite seems to be very durable, as numerous structures in Cambridgeshire, Suffolk, and the Isle of Ely now amply testify. The Ketton stone presents a very similar appearance to the last-named, but is more difficult to work. In London, the tower of St. Dunstan's-in-the-East exhibits its capabilities in a favourable light. The Ancaster stone, commonly employed in the Midland Counties, has many recommendations, not the least of these being its pleasing appearance, and the facile manner in which it may be worked. The Isle of Portland furnishes the metropolis with one of its best building stones, although it is very variable. As regards durability, the samples obtained from the West Cliff quarries are habitually superior to those got from eastern workings. A cubic foot of the Portland oolite weighs ordinarily about 149 lbs. and its crushing load is approximately 3270 lbs. per inch super. For many purposes the upper beds are preferred, from the more crystalline character of the carbonate of lime, which acts as the cementing material of the whole. Somerset House and many city churches evidence the enduring nature of Portland stone. Mr. Burnell dismisses Bath stone with a very cursory notice—the restoration of Henry the Seventh's chapel being cited as an example of its decay. It weighs, we are told, about 123 lbs. per cubic foot, and may be crushed by from 1800 to 2000 lbs. on the inch. Caen stone — so called from the Norman town of that name near which it is dug — is a very beautiful material, easily cut and carved, weighing about 120 lbs. per foot cube, and capable of sustaining nearly 2000 lbs. on the superficial inch. The upper beds of the Caen quarries yield but small blocks, but these are of a more lasting nature than those obtained at greater depths, and the Lecturer regretted that the architectural requirements of the present day should lead to the abandonment of the really good stone for that of inferior quality and of larger size. He was of opinion too that many other Norman stones possessing valuable qualities had been as yet entirely overlooked by our builders. The Purbeck stones were lastly noticed, but without presenting any point of interest for our readers. Mr. Burnell then proceeded to consider the causes of decay in building stones, which he described as partly mechanical, and in part also chemical; the solvent properties of atmospheric moisture — the variations of temperature — the integral changes of the stones themselves, as being among the most important. It was pointed out that water holding free carbonic acid in solution would ever have a destructive influence upon stones, exposing the silicates of potassa or soda, and the carbonates

of lime, &c. to its influence, but at the same time the result is greatly modified by the mechanical characters of the material. As a rule those stones or portions of stones which are crystalline, do not give way so readily as those of more amorphous nature; *volcanic* or *plutonic* crystallisation being even more permanent than any other kind. From these premises it follows that stones of an irregular, porous and earthy texture should be exposed as little as possible in situations where rain-water may lodge or beat against them, denser and more crystalline materials being employed for such places. Great stress too was laid upon the necessity of placing all stones *bedwise*, to avoid as far as practicable, the disintegrating effect of frost, &c. The chemical reactions occurring internally were stated to be mainly those of oxidation and hydration of the various constituents of the stones; but as our author at this place gets somewhat out of his depth, he will perhaps excuse our following him into what he designates "this interesting but obscure branch of applied chemistry."

Further on, he observes:

"The actions sufficient to affect the stability of the compound of ordinary building stones, by reason of the new forms of matter they superinduce, may principally be considered to be those resulting from the absorption of the gases of the atmosphere, and especially the extraordinary process known by the name of 'saltpetering,' or more correctly speaking, of nitrification. This process displays itself in the formation of minute crystals, effloresing from the interior to the exterior of the stone, and it leads to the destruction of the exposed surfaces of the latter, through the gradual removal of the minute particles, in consequence of the disintegration produced by the expansive action of the crystals in process of formation."

The causes of "salt" efflorescences Mr. Burnell evidently considers among the *obscure branches*, as he vaults lightly over that part of his subject. We turn finally to the preservative processes now used, or recommended. Paints, at the best, have but a temporary value, since the coating does not long remain intact. The application of fatty or resinous matters seems to be effectual in some cases by filling up the pores of the stone or other material, and thus protecting it in a greater or less degree from the action of air and moisture. Mr. Burnell next considered the value of various silicating processes, more particularly those of M. Kuhlmann and Mr. Ransome, which are quite similar, with the exception that by Ransome's process the stone is treated with a second wash of chloride of calcium, whereby a hard and durable silicate of lime is formed at once. On the other plan, viz. the use of soluble silicates alone, the hardening process is a very slow one, depending upon the action of atmospheric carbonic acid, and a large part of the silicate of potassa or soda gets washed away in the interim. The Lecturer regretted that the stone for the Parliament Houses had been mainly chosen from the indication of Brande's test, which cannot always be depended upon, and believed Ransome's method of preservation to be the best hitherto proposed.

The Chairman, in inviting discussion upon the paper which had just been read, said that the subject it treated of was a very important one. He thought Mr. Burnell considered it more easy to distinguish between good and bad stone than is actually the case, and could have wished that he had dwelt more upon the numerous varieties and characters of the Bath stones. The new front of Buckingham Palace was a lamentable instance of inferior Caen stone, being in its present condition a constant source of danger and expense. He watched with great interest the effect of Ransome's process, of which he thought well.

Prof. Ansted confined his remarks to two points, the causes of decay and means of preservation. There could be no doubt that the decay of granite arose from the decomposition of felspar, those varieties containing soda being more liable to change than those where potassa replaces that base. Limestones were chiefly disintegrated from mechanical causes. The dolomite limestones varied greatly in their nature, as the relative proportions of the carbonates of lime and magnesia were different: so long as these stones were *crystalline* he considered them among the very best. The quarry from which the stone for the Houses of Parliament was first taken was unfortunately not in a condition to yield the required amount, so other quarries were had recourse to, with greatly inferior results. Sandstones, he said, depended upon the durability of their cementing material, and in common with many others should always be laid *bedwise*. The mode of preservation was an easy thing to talk about, but was very difficult to accomplish, as although moisture might be prevented from entering a stone, it could seldom be got dry in the first instance. The Professor alluded in detail to the mechanical effects of water, and the solvent action of carbonic and sulphurous acids, concluding his speech with a review of the silicating processes before mentioned, and expressing a high opinion of the durability of silicate of lime.

Mr. C. H. Smith's observations were chiefly for the purpose of defending the conduct of the Commissioners appointed to select the stone for the Parliament Houses, and of correcting some statements of Mr. Burnell on this subject. He thought that "saltpetering" must come from the brickwork behind, and not from the stone itself, as he had subjected limestones to severe tests with alkalies and salts, but little effect having been produced, as his specimens would show. We may here remark that the specimens in question were marbles or crystalline stones, and therefore, from these and other circumstances, we do not consider the experiments of the slightest practical or scientific value. Mr. Smith entirely distrusted analyses, and their indications in reference to the properties of stones, saying that "Nature found out means of decay which the most scientific chemist never thought of."

Mr. Robert Hunt wished to correct an error which the author of the paper and the previous speakers had fallen into, relating to the decay of granite. He was prepared to maintain that this was *not* due to the decomposition of the felspar. China clay was *not* produced from decomposed felspar, and as far as human observation could go, never had been true granite. He dwelt at length upon one cause of decay which had been overlooked, viz. the property of all porous bodies of condensing gaseous exhalations internally, referring especially to Prof. Graham's investigations on *osmosis*. After a few observations by Prof. Tennant and Mr. Warrington, a vote of thanks was passed to Mr. Burnell. Owing to the lateness of the hour Mr. Wentworth Scott did not detain the meeting by any further remarks, but embodied his views upon "salt efflorescences" in a letter to the Secretary.

CAVENDISH SOCIETY.

The Thirteenth Anniversary Meeting of this Society was held at the rooms of the Chemical Society, Burlington House, on Thursday the 1st of March, at 3 o'clock P. M.

The Master of the Mint, *President, in the Chair.*

The Secretary read the following Report of the Council.

In the last Annual Report, the Council stated that the thirteenth volume of Gmelin's *Handbook of Chemistry* was then in progress, and was intended as a book for 1859. The completion of this volume has occupied a longer time than was anticipated, partly in consequence of the editor having to wait for a portion of the German edition which is comprised in it, and partly in consequence of the extensive additions of new matter which had to be made in the form of appendix. It is now ready for distribution, and the large amount of matter it contains, will, it is hoped, compensate in some degree for the unavoidable delay that has occurred in supplying it to the subscribers.

The Council are unable to hold out the prospect of any other volume being supplied for 1859, and must refer to the statement made in the last Report for an explanation of the

causes which have contributed to limit the issue of books during the last two or three years.

The propositions, originating from several sources, which have been made with reference to works thought to be suitable for publication by the Society, and some of which were referred to in the last Annual Report, have received the attention of the Council, and have been fully discussed on repeated occasions. The conclusion to which the Council have arrived, after mature consideration, accords with the opinion expressed in the Report of last year, which is, that the whole of the resources of the Society should be concentrated upon the completion of the few remaining volumes of Gmelin's *Chemistry* before any other work is undertaken. This opinion, they have reason to believe, is also in accordance with that of the majority of the members of the Society. In the present state of the Society, the attempt to bring out any other work in conjunction with the *Handbook of Chemistry*, would necessarily retard the completion of the latter, as the means at the disposal of the Council are insufficient for the production of more than one large volume a year, while an apparently insurmountable obstacle is presented to the extension of the number of subscribers by the necessity imposed on new members to provide a large number of the preceding volumes of the work now in progress, in order to make their sets complete. Attempts have been made to overcome this difficulty, but without success; and even if, in other respects it were possible, the small stock of the early volumes left on hand, would so far limit the power of enlarging the Society in that way, that no sufficient increase could be derived to justify any material augmentation in the expenses of publication.

The present income of the Society, if maintained, will be sufficient to enable the Council to bring out what remains to complete the work of Leopold Gmelin as fast as it is produced by the German editors; and at the same time to add, in the form of an appendix, all new matter relating to those parts of organic chemistry treated of in the preceding volumes. The matter thus added to the volume now in course of distribution, occupies two hundred pages. These additions, which are made to each succeeding volume of the work, may be regarded as "Annual Abstracts of Papers on Chemical Science," which some of the members of the Society suggested to the Council, in a communication noticed in the last Report, as suitable for publication. The Council are glad to be enabled thus far to meet the wishes expressed by members, without retarding the progress of the work which all seem desirous to expedite, or involving the Society in liabilities beyond the current means.

A new part of the German edition of the *Handbook* has just appeared, the translation of which will at once be proceeded with, and there is every reason to believe that the supply of matter will be kept up, so as to admit of the publication of a volume, with the usual additions, or abstracts of papers, every year, until the completion of the work.

The preparation of an index to the whole of the volumes is now occupying the attention of the Council.

When Gmelin's work has been brought to a conclusion, a suitable opportunity will be presented for considering the course to be pursued with reference to the future. The obstacle to the extension of the Society, to which allusion has been made, will then cease to exist. New works may be undertaken, for the selection of which ample time will have been afforded. These may resemble in character the works previously produced, or it may be thought desirable to undertake works of a different description, which would attract a new class of members, and the extension or reconstruction of the Cavendish Society would be the probable result.

The Council feel, however, that they cannot too strongly impress upon the members the importance of retaining the support of all the present subscribers to the Society, until the work on which they have been so long engaged is brought to a satisfactory conclusion.

It was moved by Dr. Roscoe, the Local Secretary for Manchester, seconded by Mr. Daniel Hanbury, and carried unanimously: That the Report just read be received, approved, and adopted.

Before the report was adopted the meeting was addressed by Dr. Basham and another subscriber, who complained of the slowness with which the Society's books were published, and suggested that some smaller volumes might be issued while the publication of Gmelin's *Chemistry* was proceeded with, which would have the effect of keeping the subscribers together, and possibly of increasing the number.

They were replied to on the part of the Council by Dr. Longstaff and Mr. Maskelyne, the former of whom asserted that the difficulty was not so much financial as in finding suitable works to publish. The latter stated that he had entered the Council with just the same opinions as Dr. Basham, but on thoroughly investigating the affairs of the Society he had become convinced that it would not be safe to undertake any other work while the publication of Gmelin's *Chemistry* was in progress. When that work was finished the Society might be reconstituted, and the publication of others commenced.

In answer to a further question from Dr. Basham, the Secretary and Mr. Watts stated that the completion of Gmelin's *Chemistry* and the copious index would probably occupy three more volumes, and the publication extend over three more years. The last part of the work issued in Germany had but just been received, and the translation of it would be immediately proceeded with.

The thanks of the meeting were voted to the President, Council and Officers, also to the Local Secretaries.

NOTICES OF BOOKS, PATENTS, &c.

Thénard. 'Eloge historique, etc. par M. Flourens. Read before the Academy of Sciences, 30 Jan. 1860. (Moniteur, 31 Jan. 1860.)

Conspicuous on the roll of those whose genius and labours have placed them in the front rank of their fellow-men, appears the name of Louis Jacques Thénard. From the most humble origin, he became a peer of France, and died at an advanced age, full of those honours which no monarch can confer, much less take away. Our limited space precludes our presenting more than a condensed review of the interesting panegyric of M. Flourens. Prefacing his subject by a brief retrospect of the more remarkable epochs of chemical philosophy, he introduces to us Thénard at seventeen years of age, just arrived in Paris from his native Champagne, with an income of sixteen sous a day, but with a heart and will of a value beyond all calculation. Two other lads, fired with the ambition of becoming country apothecaries, accompanied him. Thénard as leader of the party soon found a garret they could occupy in common, and by his frankness and address so won the motherly heart of the landlady, that in spite of her misgivings, when contemplating the requirements of three young stomachs, she boldly accepted the youths as boarders. Thénard now proceeded with his main object. Day after day he devoured with ears and eyes the brilliant discourses of Fourcroy, and the more experimental expositions of Vauquelin, but only to make the sad discovery, which, as M. Flourens says, incapables never make, that he knew nothing. His keen perception soon showed him, that to master a non-speculative science it is necessary to learn the craft (*métier*). Now Vauquelin took pupils, but his fee was twenty francs a month. We have seen the depth of Thénard's exchequer, and to meet Vauquelin's terms was impossible. Boldly, however, he seeks the great man, tells him the whole truth, and implores to be taken if only as a servant. Vauquelin refused; but that same impetuous candour which had already done him so great service, again touched the heart of woman, and found in it a sympathising advocate. The intercession of Vauquelin's sisters gained him what he sought, and for three long years he devoted himself to the drudgery of the laboratory, working, observing, and never ceasing to hope

for a brighter lot. A memorable event was at hand. Vauquelin had entrusted to his chief assistant the task of analysing a specimen of beryl. Thénard's assistance was required. The report was that the mineral contained nothing but what was already known. Vauquelin, greatly doubting it, ordered the whole to be done over again. In the mean time Thénard had collected all the materials of the first inquiry, and at the end of a month he presented to his astonished master a new substance. The final analysis was placed in his hands, and the result was a beautiful specimen of *glucina*. The discovery, Vauquelin made known to his class, at the same time loading his young assistant with praise, and propheeying his future eminence.

A professorship in an institution was soon offered to him through Vauquelin's interest, and with a view to overcome his provincial accent and manner, he attended the theatre as often as he could scrape together the necessary thirty sous. For a few days he occupied a position, honourable, but painful from his youth and inexperience, as Vauquelin's substitute, and venturing at his fifth lecture to raise his eyes, the sight of his master and Fourcroy put him to flight. We soon find him installed as a teacher in the Polytechnic School, a post which gave him leisure to produce some original memoirs, the first of which, read before the Academy in 1799, was the precursor of a series extending over more than half a century. We can only indicate as among the labours of his earlier years investigations relating to organic chemistry, the metallic oxides and the ethers, nor should we omit the discovery of artificial ultramarine. Then sprung up imperious demands for material of war, and in the prosecution of military chemistry Thénard and Gay-Lussac became inseparable friends under the roof of Berthollet. But amid the din came the tidings of Davy's great discovery of potassium and sodium, and it is but justice to record, that notwithstanding the war, the great English philosopher was invited over to receive the prize awarded by the Institute. But Napoleon was not well pleased. "Do you mean to endure that victory of the English?" he said impatiently to Berthollet. A huge battery was forthwith constructed and entrusted to Thénard and Gay-Lussac. They soon however, announced that, by availing themselves of the ordinary chemical affinities, they could separate the new metals more easily than by the battery, and they succeeded in isolating a new body, which they called *boron*. Davy elaimed the new substance, which he said he had seen the year before. Thénard and Gay-Lussac would not concede the priority of discovery, and at the same time contended that sodium and potassium were not simple bodies, but combinations of the alkalies with hydrogen — *hydrides* in fact. Davy replied that if they held this theory, they must allow that their *boron* was only a *hydride of boracic acid*. There was no reply to this. A long controversy afterwards followed which, among other things, led Davy to the discovery of the true nature of chlorine.

A constantly increasing reputation was crowned by Thénard's elevation to the chair of Fourcroy. He now married, and then commenced a course of prosperity due alike to his labours, to his marriage, and to his good management, resulting in the accumulation of a large fortune. Precision was one of Thénard's characteristics, and the want of it in his assistants elicited another—an excitable temper. If an experiment failed or was not ready at the moment, the delinquent was overwhelmed with a storm of reproaches, and even, it is said, got his ears boxed occasionally. But his goodnature was always at hand, and he would apologetically observe that Fourcroy had often treated him in like manner, and that it sharpened the wits. We read how his own sharpness availed him in his discovery of the binoxide of hydrogen in 1818, a discovery which attracted many chemists to Paris, and among them Berselius, between whom and Thénard an immediate intimacy sprung up. We are amusingly told how, soon after their interview, when Thénard was progressing brilliantly with his lecture at the Sorbonne, he happened casually to look towards a corner of the theatre. Immediately he began to hesitate, and at last broke down. "Gentlemen," he said in explanation, "there is Berzelius." The solemn Swede was forthwith carried in triumph to a seat near the chair, exclaiming in his progress that it was impossible not to be a good professor with such pupils. We may imagine the gratification of the warm-hearted Thénard. A striking evidence of that generous nature was shown when he was told that Charles X. had created him a baron. "And why not Gay-Lussac too?" he inquired; "he deserves it as well." When again the paintings with which Gros had adorned the dome of the Panthéon were ruined by the damp permeating the stone, Thénard, full of compassion for Gros, devised a plan which was so well received at the Tuileries, that a royal promise was made of which he felt assured he should never avail himself. But the occasion came. A section of a mob flying before the police had contrived to slip into his theatre, which after lecture was discovered surrounded by a guard prepared to arrest all who came out. Thénard's proposal of a sifting process was agreed to with difficulty. Those who had notes were allowed to pass, those who could answer a chemical interrogatory likewise. But fifty, who had no notes and could give no answers, were marched off to prison. The sight was too much for Thénard. He runs to the minister of the interior, to the prefect of police, but without success. Suddenly he remembers the promise of the king, rushes to the Tuileries, after some difficulty obtains an audience, and at midnight is at the prison door with an order for their release. "You can go, Messieurs," he exclaims; but stopping suddenly he adds: "On one condition—you must all study chemistry." We must relate an accident at lecture which threatened serious consequences. He drank what he supposed to be some water. Discovering his mistake, he calmly said, "Gentlemen, I am poisoned. Fetch me some eggs." It was a solution of corrosive sublimate he had swallowed. Inflammation of the stomach supervened, and for many days he lay in great danger, his house the while surrounded by a triple chain of students, who day and night preserved the profoundest tranquillity in the neighbourhood. When he reappeared in his place the universal joy passed all bounds. But the shadows now began to fall fast on his declining years. The death of his mother-in-law was followed by that of his wife and youngest child. A brother, a sister, a nephew were next lost to him, and except for an only son, on whose life he dared hardly depend, the brave old man was left alone in the world. At eighty years of age he followed those whom he had loved so well. But before he died his benevolent heart had originated a noble project, and the widow, the orphan, and the struggling student in generations to come will learn in their hour of need to bless and honour the name of Thénard.

A Composition named Zeiodelite, a kind of Paste which becomes as hard as Stone, is unchangeable by the Air, and being proof against the action of Acids, may replace Lead and other substances for various uses. Joseph Simon, 1859.

Zeiodelite is made by mixing together 19 lbs. of sulphur and 42 lbs of pulverised stone ware and glass. The mixture is exposed to a gentle heat, which melts the sulphur, and then the mass is stirred until it becomes thoroughly homogenous, when it is run into suitable moulds, and allowed to cool. This preparation is proof against acids in general, whatever their degree of concentration, and will last an indefinite time. It melts about 120° Centigrade, and may be re employed without loss of any of its qualities, whenever it is desirable to change the form of an apparatus, by melting at a gentle heat, and operating as with asphalte. At 110° Centigrade it becomes as hard as stone, and therefore preserves its solidity in boiling water. Slabs of zeiodelite may be joined by introducing between them some of the paste heated to 200° Centigrade, which will melt the edges of the slabs, and when the whole becomes cold it will present one

uniform piece. Chambers lined with zeiodelite in place of lead, the inventor says, will enable manufacturers to produce acids free from nitrate and sulphate of lead. The cost will be only one fifth the price of lead. The compound is also said to be superior to hydraulic lime for uniting stone, and resisting the action of water.

CORRESPONDENCE.

The Connection between the Atomic Theory and the Divisibilty of Matter.

To the Editor of the Chemical News.

Sir, — The following considerations may do something towards throwing this question into a more intelligible form. There can be no doubt that, at any rate mechanically, the divisibility of matter has some practical limitation; and that, beyond this, no human agency can carry the subdivision further. I apprehend that no person can consider this, and pronounce himself unsatisfied as to its truth. But when we come to chemical combinations, more especially where their mathematical precision is formally evident, which is the case in crystallised substances, the universality of the former proposition is not so evident. The perfect regularity here witnessed, seems to prove that these substances are composed of infinitely small particles; and the same idea arises from the diffusibility of various salts, and other phenomena.

But here I use a term which I do not pretend to understand, and which I apprehend never has been and never will be understood. The term infinite is one which, it appears to me, the human mind will never be enabled to comprehend. This is not the place for entering into a discussion upon the matter; and I shall only remark that it may be found fairly argued in the pages of Locke. Forming, however, the best idea we can of infinite, and it is but a miserable approximation after all, I would urge whether we can suppose water and other chemical compounds to be the union of atoms, which *per se* are such; and whether a less difficulty applies to the constituents of other bodies.

However unable man may be practically to reduce bodies beyond a certain size, which however may be termed, and is in reality, indefinite, I maintain that the infinite divisibility of matter is, at any rate, as far as theory goes, at once according to human reason. In fact the opposite idea is at once theoretically absurd. But upon meeting the experimental view of the question, a rather unmanageable difficulty rises before us; and we are the worse off from being obliged to grapple with a term which we so meagrely apprehend. However difficult it is to conceive that water is composed of a countless number of infinitely small atoms, it is surely far more difficult to understand how the formation of crystals can result from the union of bodies, which, reason causes us to believe, are similarly constituted. We cannot help reflecting how a finite power, in this case that of chemical affinity, can work upon infinity in number; and the same difficulty awaits us upon the consideration of size. It is true that the space occupied is finite, but this in no way lessens the difficulty, making it in fact more mysterious; because we see that a circumscribed amount of space contains two infinites, those regarding size and number, and that even infinite space could, as regards the atmosphere, we may say does, contain no more. I think a profound consideration of the matter will hereafter convince all philosophers that the finite powers of nature work upon bodies, or collections of forces, taking matter to be nothing more, infinite both in size and number. Priestley, adopting this hypothesis of Boscovich, has (*Disq. on Matter and Spirit*) somewhat elegantly illustrated it. It is evident that any assignable portion of matter, or collection of forces or powers, is capable of decrease: hence any really definable atoms or particles may be divided, which is against the radical idea of such, and consequently destroys them. It should be observed, that infinitely small particles are not assignable, or capable of being numerically defined; while others, if incapable of division practically, can by supposition be divided. But no person will undertake to suppose, much less divide, or in any way represent, the half of an infinitely small atom. In applying these remarks to the atomic theory, I think it only necessary to urge that the atoms there for convenience supposed to exist should be considered numerically undefinable. By considering them infinite I apprehend that a scientific formula would be replaced by a philosophical reality, and that the purpose the former now serves would in every way be supplied by the latter —I am, &c.

J. A. Davies.

To the Editor of the Chemical News.

Sir, — I should feel very much obliged if you would advise me what works are suitable to read up for the second B. Sc. London University examination. Where time is valuable, it is important not to waste it in perusing books not exactly fitted for any particular examination.—I am, &c.

Inops.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

Zinc Ore in the form of Oolite.—In a zinc mine near Udias, in the province of Santander, Spain, two cavities were broken open, one of which was found filled with a clear zinc solution, and in the other was a quantity of zinc ore in the form of oolite. It consisted of granules arranged in concentric layers, which on being broken often split into thin plates. The outer layers were opaque and milk white, while the inner were transparent and glossy, so that the granules looked like fishes eyes. It is remarkable that the granules coming from the same vein should not have the same composition; but some were found to consist of a basic hydrated oxide and carbonate of zinc, and others were a hydrated silicate. The carbonate had the specific gravity of 2·042, and the silicate 2·762. Both minerals contained a little nitrogenous organic matter. Both were soluble in acids, the silicate giving gelatinous silica. The carbonate had the following composition:

ZnO	58·93
$ZnO.CO_2$	34·72
$CaO.CO_2$	2·85
$Al_2O_3.Fe_2O_3$	0·80
HO	12·40
Hygroscopic water	3·13
Organic matter	a trace

The formula is:

$$2(ZnO.HO) + ZnO.CO_2.$$

The silicate has the formula:

$$2[ZnO.SiO_3 + 3(ZnO.HO)] + ZnO.CO_2.$$

Its analysis gave:

$ZnO.SiO_3 + \left.\begin{matrix}\\ ZnO.HO\end{matrix}\right\}$	83·93
$ZnO.CO_2$	10·36
$CaO.CO_2 + Al_2O_3 + Fe_2O_3$	0·46
Hygroscopic water	5·16
Organic matter	a trace.[1]

The Atomic Weight of Lithium.—W. Mallet[2] has determined the atomic weight of lithium by means of the decomposition of sulphate of lithia by chloride of barium. He calculates from the amount of chloride of barium required to precipitate the sulphuric acid for lithium as the mean of four experiments Li = 7·005, or 7, considering H = 1, and 87·5, if O = 100.

[1] *Terreil, Comptes-Rendus*, t. xlix. p. 553.
[2] *Silliman's American Journal*, v. xxviii. p. 351.

II. ORGANIC CHEMISTRY.

Compound of Oil of Bitter Almonds and Chloride of Calcium. — If powdered chloride of calcium is added to pure oil of bitter almonds the mixture solidifies with development of heat. If only a small quantity of chloride of calcium is added, crystals are soon deposited, which are speedily decomposed. Two specimens quickly pressed and weighed gave on analysis 19·8 and 23·4 of calcium. These members correspond to 2·5 and 3·3 molecules of chloride of calcium to 1 molecule of bitter almond oil.[3]

Action of Chlorous Acid on Organic Matters. Schiel has observed[4] that ethylic and amylic alcohols when treated with chlorous acid are changed into acetic ether and valero-amylic ether, perfectly free from chlorine:

Acetic ether.

$$2\left.\begin{matrix}C_4H_5\\H\end{matrix}\right\}O_2 + ClO_3 = \left.\begin{matrix}C_4H_3O_2\\C_4H_5\end{matrix}\right\}O_2 + 3HO.Cl.$$

Valero-amylic ether.

$$2\left.\begin{matrix}C_{10}H_{11}\\H\end{matrix}\right\}O_2 + ClO_3 = \left.\begin{matrix}C_{10}H_9O_2\\C_{10}H_{11}\end{matrix}\right\}O_2 + 3HO + HCl.$$

Caprylic alcohol behaves differently.

Urea is slowly decomposed in contact with a solution of chlorous acid, and carbonic acid is disengaged. By evaporation on a water bath a crystalline mass is obtained, which is purified by solution in alcohol and re-crystallisation. The crystals are acid, but they decompose when heated to 165° and give off ammonia. On analysis they were found to have the composition expressed by the formula:

$$C_3H_8N_3ClO_2$$

which would indicate that the new body was a combination of urea and chloride of ammonium:

$$\left.\begin{matrix}C_2O_2\\H_4\end{matrix}\right\}N_2 + NH_4Cl.$$

The reaction may be thus explained:

$$2\left(\left.\begin{matrix}C_2O_2\\H_4\end{matrix}\right\}N_2\right) + ClO_3 = \left(\left.\begin{matrix}C_2O_2\\H_4\end{matrix}\right\}N_2 + NH_4Cl\right) + C_2O_4 + NO.$$

The behaviour of the new body with nitric acid does not support the idea of its being a compound of urea and sal ammoniac. Its alcoholic solution gives with nitric acid a precipitate of scaly crystals, but slightly soluble in cold alcohol, which after washing with spirit and drying have a beautiful mother-of-pearl lustre, and on analysis are found to contain chlorine. The same body cannot be obtained by crystallising together like proportions of urea and sal ammoniac.

With uric acid chlorous acid gas produces a new acid, which the author calls *chloraluric acid*. An aqueous solution of chlorous acid is used, which is added by degrees to the uric acid until nearly all the latter is dissolved, and the solution has acquired a greenish colour; it is then poured off the undissolved uric acid and evaporated on a water bath. The white mass left is then dissolved in hot alcohol of 90 per cent., and on cooling the chloraluric acid separates in nacreous scales. It is soluble in water, and the solution has a strong acid reaction. Combined with soda or potash it gives a crystalline precipitate with the nitrates of baryta and lead, and a curdy precipitate with nitrate of silver. The silver and lead precipitates are insoluble in water. On analysis the acid was found to have the composition $C_{14}H_{11}N_6ClO_{11}$. When an excess of chlorous acid is used, two other bodies are formed, one an amorphous yellow, and the other a reddish brown crystalline substance; but these the author has not well examined.

Action of Organic Chlorides on Glycol, &c. — M. Lourenço says that the chlorides of acetyle and butyryle act on glycol with great energy at the ordinary temperature with the disengagement of hydrochloric acid and the volatilisation of part of the chloride. If the mixture be made in a cooled tube it may be sealed before the action begins. The products obtained by making use of the chloride of acetyle and heating for some hours in a water bath are water and a limpid chloride heavier than water, which possesses all the properties of chloracetine. If the mixture is made at the ordinary temperature and the hydrochloric acid is allowed to escape before sealing the tube, the monoacetic glycol is obtained besides.[5]

III. TECHNICAL CHEMISTRY.

Behaviour of Coal Gas with Fatty Oils. — Coal gas is a mixture of elayle with various hydrocarbons, some of which the author supposed might be withdrawn by means of fatty oils, which experiments proved to be the fact. He passed dry coal gas through a potash apparatus filled first with almond oil and then with lamp oil. The gas was allowed to pass until there was no further increase of weight. The weight of the almond oil was found to be increased by 9·3 per cent., and lamp oil as much as 20·5 per cent. The illuminating power of the coal gas did not appear to be lessened, while that of the lamp oil was considerably increased. Wax, tallow and stearine exposed for some time to the influence of gas seemed to absorb a large quantity of it and to become soft. The above experiment might be turned to account in improving the illuminating quality of the fatty oils.[6]

Yellow Dye from Catechu. — If powdered catechu is treated with nitric acid at a temperature of 113° F. until nitrous acid is no longer evolved, a yellow substance is obtained with exactly the same properties as picric acid, and moreover is more soluble in cold water. Silk and wool may be very easily dyed with a cold solution. Silk is instantly coloured, but wool requires a longer time. To produce the yellow powder the best brown catechu must be employed. It is unimportant whether the nitric acid is poured on the catechu or the catechu is stirred into the the nitric acid.[7]

Analysis of Porcelains. — Joseph Muller[8] publishes analyses of several celebrated porcelains. The various kinds found in commerce show the greatest differences in their physical properties, on which account one or another seems especially adapted for chemical and pharmaceutical purposes and is preferred to all the others. With a view to discover how far these properties depend on the composition, the author analysed several porcelains. The results were as follows:

	I. Meissen porcelain.	II. Elgersburg.	III. Bohemian.
Silica	60·033	72·77	74·798
Alumina	35·435	24·53	21·303
Potash	2·264	0·94	2·484
Soda	1·547	1·61	0·584
Lime	0·577	—	0·639
Magnesia	trace	trace	trace
Peroxide of iron	trace	trace	—
Sulphuric acid	—	0·06	0·087
	99·856	99·91	99·895

For comparison the author adds the analysis of Nymphenburg porcelain by Vielguth, and of Berlin by Wilson:

	I. Nymphenburg.	II. Berlin.
Silica	72·80	71·340
Alumina	18·40	23·763
Peroxide of iron	2·50	1·743
Lime	3·30	0·568
Magnesia	0·30	0·192
Soda	1·84	—
Potash	0·65	2·001
	99·79	99·607

SCIENTIFIC NOTES AND QUERIES.

Lead in Filtering Paper. — Sir,—Whether it be true or not that lead is occasionally to be found in filtering paper, as stated in your "Notices from Foreign Sources," is not of much importance. The careful toxicologist would no doubt well wash his paper with dilute nitric acid before filtering a suspected liquid. At all events now that it has been shown that lead may be present, it would be well to do so. The discovery of lead, however, suggests the possibility of more important contamination, which will no doubt receive the serious attention of analysts.—*G. M.*

MISCELLANEOUS.

Amount of Tannin in some Materials. — The following table we have taken from the *Irish Agricultural Review*. The names Mulligan and Dowling are those of two chemical students belonging to the Museum of Irish Industry in Dublin. Their analysis is quite recent, and will be very interesting and useful to our tanners:—

	Per cent.	*Authority.*
Oak bark formation, 100 years old	8·45	G. Muller.
" young	13·87	"
" British, 50 years old	8·90	Mulligan and Dowling.
" " age about 50 years	9·76	" "
" " " 70 years	6·12	" "
" Southampton, age about 50 years	8·80	" "
" coppice, picked sample	12·35	" "

Recipes for making Coloured Inks.—The following are a few recipes for making coloured inks, which may be used by fancy writers; and as they are not to be found on sale, they may be very useful to some of our readers:—

Gold Ink. — Mosaic gold 2 parts, gum arabic 1 part, are rubbed up with water until reduced to a proper condition.

Silver Ink.—Triturate in a mortar equal parts of silver foil and sulphate of potassa, until reduced to a fine powder, then wash out the salt, and mix the residue with a mucilage of equal parts of gum arabic and water.

Brown Ink.—Digest powdered catechu 4 parts, with water 60 parts, for some hours; filter and add sufficient of a solution of bichromate of potassa, 1 part in 16 of water.

Yellow Ink.—Macerate gamboge 1 part (or 1½), alum ½ part, gum arabic 1 part, in acetic acid 1 part, and water 24 parts.

Blue Ink.—Triturate best Prussian blue 6 parts, with a solution of 1 part of oxalic acid in 6 of water, and towards the end of a quarter of an hour or so add gradually gum arabic 18 parts, and water 280. Pour off clear

Red Inks. — 1. Pernambuco wood 4 parts, alum and cream of tartar, of each 1 part with 30 of water; boil down to 16 parts, let stand, pour off, filter and dissolve in the liquid, gum arabic 1½ parts, white sugar 1 part.

2. Digest powdered cochineal 8 parts, and carbonate of potash 16 parts in 144 of water, for 24 hours. Then boil up with powdered alum 4 parts, and add 24 of cream of tartar, with 3 parts of tartaric acid, and when effervescence has ceased, another part of the acid, or enough to produce the colour. Let cool, filter, and boil the residue on the filter with 12 parts of water: filter again, mix the liquids and dissolve in them 24 parts of gum arabic, and lastly ½ part of oil of cloves. No iron vessels must be used in this process.

3. Digest powdered cochineal 16 parts, oxalic acid 2 parts, dilute acetic acid 80 parts, distilled water 40 part for 36 hours. Then add powdered alum 1 part, gum arabic 1 to 10, shake up, let stand for 12 hours and strain.

4. Dissolve 1 part of carmine in 8 to 10 parts of aqua ammonia, and add mucilage of gum arabic sufficient to reduce it properly.

Violet Ink. — 8 parts of logwood and 64 parts of water; boil down to one half, then strain and add 1 part of chloride of tin.

Green Inks. — 1. Digest 1 part of gamboge with from 7 to 10 parts of the blue ink.

2. To powdered bichromate of potassa 8 parts, contained in a porcelain dish, add oil of vitriol 8 parts, previously diluted with 64 of water; then heat, and while evaporating add gradually 24 parts of alcohol, and reduce to 56 parts, which filter, and in the clear liquid dissolve 8 parts of gum arabic.

Crimson Ink.—A beautiful crimson ink is made by mixing red ink No. 1 with the violet ink: about equal parts will answer.

The parts given are those of weight, not measure. The mucilage of gum arabic prevents the fine particles of colour falling to the bottom in the form of a sediment. Sugar gives to inks a glossy appearance, but very little of it should be used, as it is liable to make the ink sticky.

Duty on Chloroform. — Chloroform has been struck out of the list of articles to be admitted free of duty.

ANSWERS TO CORRESPONDENTS.

*** In publishing letters from our correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

W. T. L. — The methods of making putty powder will be found in *Cooley's Cyclopædia of Practical Receipts.*

Excelsior. — *Hassall's Adulterations of Food and Drink*, 12*s*. *Electrotype Manipulations*, parts I. and II. or *Manual of Electro-Metallurgy*, by Napier, 3*s*. 6*d*.

A Constant Subscriber. — The decay of various parts of a plant is at times accompanied by a peculiar decomposition resulting in the development of a substance which, like phosphorus, burns at the ordinary temperature producing light. It must be considered as a peculiar and easily combustible compound of carbon, hydrogen, and oxygen. See Gmelin's *Chemistry*, vol. i. p. 191. A scale of graduated shades is painted to serve as a standard of comparison. Ozone is supposed to be oxygen in a peculiar state. See Chemical News, No. 10, p. 109.

M. A. B.—We are not at liberty to divulge the name or address of the writer of the letter alluded to. The author is *not* the gentleman whom you have mentioned. We will forward any communication which you may have to make to the writer.

W. H. (Tillydesk) —By "next week" we intended to intimate that a reply would be given on the following week, but unfortunately the matter escaped our notice. The opinion as to the value of the process was quoted from Dr. Noad, who is certainly a good authority on such matters.

S. E. (Birmingham)—It could only be made into bricks by powdering it finely, moistening with water, and pressing into moulds. On the other point our correspondent will receive a private communication.

M. P.—The title of the book, we think, is *The Art of making Perfumes*, by Septimus Piesse. There is an American work on the same subject by Morfitt, but it is larger and more expensive.

Anode.—Electricity has never been made use of as a motive power on a large scale. See Liebig's *Letters* for Comparative Cost of Steam and Electricity.

J. M. F. (Chelmsford) — The last edition of Fowne's *Manual of Chemistry*.

J. Gordon—Tyro—R. A. C.—W. J. J.—received — answers next week.

Erratum.—Page 153, line 20, for 14 read 1·4.

*** All *Editorial Communications* are to be addressed to the Editor; and *Advertisements* and *Business* communications to the Publisher, at the Office; 12 and 13 Red Lion Court, Fleet Street, London E. C.

THE CHEMICAL NEWS.

VOL. I. No. 15. — March 17, 1860.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On Numerical Relations existing between the Equivalent Numbers of Elementary Bodies, by CAREY LEA.[1]

IT is evident that the number 44—45 plays an important part in the science of Stoichiometry. If we form a descending arithmetical series beginning with antimony =120·3 and diminishing by common difference of 45 (45·3 in one instance, and 44 in several) we shall find that such a series does not cease with the third term P=31; but that the difference of 31 and 45 will give a fourth—14 the exact equivalent of nitrogen with the negative sign. The fifth will be —59 the equivalent of tin with the negative sign. The sixth —104, or very nearly the equivalent of lead. The seventh —149, very nearly the double of the equivalent of arsenic, a previous term in the same series. These results are exhibited in the following table:

Differences.		Calculated Equivalents.		Received Equivalents.
45	. .	120	. .	Sb = 120·3.
	. .	75	. .	As = 75.
44	. .	31	. .	P = 31.
45	. .	−14	. .	N = 14.
45	. .	−59	. .	Sn = 59.
45	. .	−104	. .	Pb = 103·5.
45	. .	−149	. .	2As = 150.

The relations can be carried still further — the ninth term giving —239 or 2Sb=240·6; and the thirteenth, —416 or exactly 2Bi=416.

If we examine the position occupied by antimony, arsenic, phosphorus and nitrogen in the electro-chemical scale of Berzelius, we shall find that in proportion as their equivalent numbers diminish, their properties become more and more electro-negative; a corresponding change is also visible in the organic radicals which these elements are capable of forming by their union with carbon and hydrogen.

Standing between nitrogen and arsenic, phosphorus is in every way more closely allied to the latter of these substances, not only by the analogies of its organic radicals, but also by the polybasic nature of phosphoric acid. Although tin and lead represent further numbers of the same series in reference to their equivalent numbers it is evident that the increase of electro-negative relations does not extend to them. Moreover bismuth, antimony, arsenic, phosphorus and nitrogen at their maximum of oxidation combine with five equivalents of oxygen and chlorine, whereas tin unites with but two of each, and lead at most with two of oxygen and one of chlorine.

Again if we begin with phosphorus and form an ascending series with a common difference of 44 or 45, we have P=31+44=75 (As). 75+45=120 (Sb=120·3). 120+44=164 (absent). 164+44=208 (Bi.) These four elements exhibit strong analogies, and are all isomorphous with each other.

If taking mercury as the starting point we subtract the number 44 from each term to find the following one, we shall obtain the (series) Hg100—44=56(Cd). 56—44=12(Mg). 44—12=—32(Zn=32·6). The salts of the protoxides of the three last of these metals are isomorphous. It may seem forced to place mercury in the same group, but its analogies with zinc are perhaps as strong as those which it exhibits with silver, next to which it has usually been classed.

It is not a little curious that the numerically negative numbers of this series lead into the positive of the foregoing: if we continue the subtraction of 44 we find for the fifth number 76, or nearly the equivalent of arsenic, for the sixth 120, or nearly that of antimony, for the seventh 164, corresponding with a possible undiscovered metal, and for the eighth 208, or exactly the equivalent of bismuth. The two series thus naturally lead to each other.

The magnesia group includes a well-marked natural family of metals, whose oxides, having the constitution Ro, are related with each other by isomorphism. The equivalents of these metals, according to the most recent determinations, are as follows: —

Mg 12	Ni 29·6	Cd 56.
Mn 27·5	U 60	Cu 31·7.
Fe 28	Cr 26·7	Pb 103·5.
Co 29·5	Zn 32·6.	

The equivalents of the above metals are related in the following manner by the number 44. Cu and Mg, Zn and Mg, the sum of each pair is 44 nearly. With Cd and Mg, Pb and U, the difference of each pair is 44 nearly. With W and Mg, W and Fe, U and Co, U and Ni, U and Cr, Cd and Zn, the mean term is 44 or nearly. With Pb and Mn, Pb and Fe, Pb and Ni, Pb and Co, Pb and Cr, the sum of each pair is three times 44, or nearly. The equivalent of Mg added to that of Zn gives 44 nearly, subtracted from that of Cd 44 exactly.

The following metals may be classed together as tending to form acids:

Sn 59	Ta 68·6	Va 68	Te 64.
Ti 25	W 92·	Mo 48	Nb 48·82.

Relations depending upon the number 44 can be shown to exist between these equivalents, and these analogies, though many are very complex, approach exceedingly near to absolute exactness. We give one or two illustrations. If we subtract Ti 25 from Ta 68·6 or V 68·8 the remainders are 43·6 and 43·8 very nearly 44.

If we add Sn 59, Ta 68·6, W 92, V 68·8, and Te 64, the result is 352·4, or 8×44=352.

If we add Ta 68·6, Mo 48, 2 Sn 118, V 68·8, Nb 48·82, we have 352·22, 8×44=352.

If commencing with gold Au=197, we form a diminishing series with a common difference of 44·5, we shall find for its terms, 197 Au, 152·5 absent, 108 Ag, 63·5 or Cu=63·4. The equivalent of Cu is here taken at double that usually employed, and it is doubtful if this be not the true equivalent. It can be shown that these metals as well as many others here grouped by relations depending upon a number approximating to 44·3 are also united by analysis of atomic volume.

The same relation may be extended to the platinum

[1] Abridged from *Silliman's Journal*, Jan. 1860.

group, which naturally subdivides itself into two families. The members of each family have nearly the same equivalents, and the difference between the equivalents of the two families approaches to 45.

Rhodium	52·2	Platinum	98·7
Ruthenium	52·2	Iridium	99·
Palladium	53·3	Osmium	99·6

The elements carbon, boron, and silicon, are united by the number 44 in following manner. If we take the equivalent of carbon as 12, and that of boron as 11, then the sum of the equivalents of these three substances amounts 44 exactly.

Carbon (C)	12
Boron	11
Silicon	21
	44

The equivalent of nitrogen added to 3 times 45, and divided by 8, gives nearly the equivalent of fluorine. In the same way, 14 added to 6 times 45 and divided by 8 gives the equivalent of chlorine. Similarly

$\frac{14+14\times45}{8}=80\cdot5\,Br=80$ | $\frac{2\times14+22\times45}{8}=127\cdot25\,I=127.$

Several elements taken in pairs have equivalents which differ from each other by a number approximating to 45. For instance:

$$Na\,23+45\cdot6=Ba\,68\cdot6.$$
$$Cl\,35+45\cdot5=Br\,80\ \&c.$$

In this way, by sometimes adding, sometimes subtracting, sometimes multiplying, sometimes dividing, and sometimes by performing all these operations together, the author finds that some relation to the number 44–45 extends to no less than 48 of the elementary bodies; to all, indeed, except those as yet imperfectly understood, most of which may yet range themselves under the same laws, and except the group oxygen, sulphur, selenium, and tellurium, substances which stand above and unmistakeably apart from the other elements.

On the Action of Chloride of Ethyl upon Ammonia[1], *by* C. E. Groves.

The action of chloride of ethyl upon ammonia not having previously been examined, the author effected the reaction by heating to 100° C. in sealed tubes a mixture of one measure of chloride of ethyl, with three measures of alcoholic ammonia. A crystalline deposit of sal-ammoniac took place, which was washed with alcohol. The washings were added to the liquid product, which was evaporated to dryness. This residue was dissolved in water, treated with oxide of silver, and the whole submitted to distillation. By this means, a small quantity of hydrated oxide of tetrethylium was left unvolatilised. This was converted into its platinum salt, and analysed. The principal constituent of the distillate was ethylamine; but by fractional precipitations with bichloride of platinum, and frequent crystallisations the presence of diethylamine was also established. It is observable that chloride, bromide, and iodide of ethyl differ somewhat in their reactions upon ammonia. The chloride produces principally ethylamine, with small quantities of di-ethylamine and hydrate of tetrethylium. The bromide produces principally ethylamine, with very appreciable quantities of of di- and tri-ethylamine; while the iodide produces the three volatile bases in about equal proportions, with an appreciable quantity of the tetrethylium compound.

PHARMACY, TOXICOLOGY, &c.

On Syrup of Superphosphate of Iron and other Phosphates used in Medicine, by Samuel Gale, *F.C.S.*

A syrup under this name was introduced to the notice of the Pharmaceutical Society as far back as 1851, by Mr. Greenish, who directs it to be made by adding as much phosphate of iron to a solution of metaphosphoric acid, as the latter in a boiling state will take up, and allowing it to cool: of this compound two scruples are added to an ounce of simple syrup. Now this compound, which has been called biphosphate of iron, is very indefinite, therefore the syrup prepared from it would be liable to the same fault. Another objection is that you have an opaque syrup with a precipitate forming after a short time, making it necessary to label the bottle "to be shaken."

In carrying out these experiments I have tried to gain three points: first, to obtain a syrup that should be definite in strength; secondly, permanently bright; thirdly, easily made. The following is the plan I adopt. Take

Protosulphate of iron		222 grs.
Phosphate of soda	q.s. or	240 „
Water		q.s.
Dilute phosphoric acid		5 oz.
Sugar	(troy)	8 „

Dissolve the sulphate of iron and the phosphate of soda separately, each in 4 oz. of water, mix the solutions and throw the pasty mass formed on a calico filter and wash well with water; then squeeze the precipitate as dry as possible, and add it to the dilute phosphoric acid. As soon as dissolved, filter the solution, which will now be found to measure about 6 oz. In this dissolve the sugar without heat, so that the product shall be exactly 12 oz. Each dram of the resulting product then contains 1 grain of $3(FeO)PO_5$, or rather more than 1¼ grain of $3(FeO)\,PO_5+8HO$ (the form which Gmelin gives for blue phosphate of iron), with 25 minims of dilute phosphoric acid. This is about equal to 5 grains of the so-called biphosphate of iron.

Syrup of Phosphate of Iron and Manganese.—This is made in a similar manner to the foregoing. Take

Protosulphate of iron		124 grs.
Sulphate of manganese (dry)		46 „
Phosphate of soda	q.s. or	240 „
Water		q.s.
Dilute phosphoric acid		5 oz.
Sugar	(troy)	8 „

Dissolve the sulphates in 4 oz. and the phosphate of soda in a similar quantity of water, mix the solutions, wash the precipitate on a calico filter and press as before. Add the precipitate to the dilute phosphoric acid, filter and dissolve the sugar without heat. The product should measure 12 oz., when each dram will contain ¾ grain of phosphate of iron, $3(FeO)\,Po_5+8\,HO$, and ½ grain phosphate of manganese, $3(MnO)\,Po_5+7HO$, with 25 minims of dilute phosphoric acid.

Syrup of Phosphate of Iron, Manganese, and Nickel, may be made in the same manner by taking:

Protosulphate of iron		124 grs.
Sulphate of manganese (dry)		46 „
Sulphate nickel		56 „
Phosphate of soda	q.s. or	240 „
Dilute phosphoric acid		5 oz.
Sugar	(troy)	8 „

Dissolve the sulphates in 4 oz. and the phosphate soda in a similar quantity of water, mix the solutions, throw on a calico filter, wash and proceed as before, making the product measure 12 oz. Each dram then contains ¾ grain phosphate iron, ½ grain phosphate manganese, and ½ grain phosphate nickel, with 25 minims of dilute phosphoric acid.

Syrup of Phosphate of Iron and Lime is at the present time frequently ordered, and the plan I have adopted in making it has been to precipitate the phosphate of iron as

in the previous syrups. Then I take a given quantity of phosphate of lime and dissolve in hydrochloric acid, and reprecipitate it with ammonia, so as to obtain it in a more soluble state than as dry phosphate. Take

Sulphate of iron	124 grs.
Phosphate of soda q.s. or	142 „

Dissolve separately, precipitate, and wash as before.

Dissolve 48 grs. phosphate of lime in a sufficient quantity of hydrochloric acid, diluted with twice its volume of water, then add ammonia: throw the precipitate on a filter and wash; dissolve the above precipitates in 5 oz. dilute phosphoric acid, and add 8oz. sugar to the clear solution, when each dram will contain ¾ grain phosphate iron and ½ grain phosphate of lime with 25 minims of dilute phosphoric acid.

Syrup of Phosphate of Iron:

Sulphate of iron	124 grs.
Phosphate of soda q.s. or	142 „

Dissolve separately, precipitate and wash; add this to 5 oz. dilute phosphoric acid, with 48grs. phosphate of soda, and in the clear solution dissolve 8oz. sugar.

Syrup of Superphosphate of Zinc:

Sulphate of zinc	429 grs.
Phosphate of soda	480 „
Dilute phosphoric acid	5 oz.
Sugar (troy)	8 „

Dissolve the sulphate of zinc and phosphate of soda separately and mix the solutions, collect and wash the precipitate; add this to the dilute phosphoric acid, then dissolve the sugar; let the product measure 12 oz., when each dram will contain 2 grs. phosphate of zinc and 25 minims dilute phosphoric acid.

There is one other preparation of the phosphates, viz. the "Syrup of Pyrophosphate of Iron." In the *Pharmaceutical Journal*, vol. xii. 498, there is a process by Soubeiran for the preparation of this syrup, by precipitating the persulphate of iron with excess of pyrophosphate of soda, the precipitate being soluble in excess of the precipitant and dissolving sugar in the solution without heat. But recently M. Robiquet has introduced a more elegant syrup, which is made by first forming what he calls a "Citro-ammoniacal Pyrophosphate of Iron," known in this country as pyrophosphate of iron. His form is the following:

Sulphate of peroxide of iron	50 parts
Pyrophosphate of soda	84 „
Citric acid	26 „
Ammonia, to neutralise the citric acid	q.s.

Dissolve the sulphate of iron and pyrophosphate of soda separately without heat, and mix the solutions: wash the precipitate and dissolve it in the citrate of ammonia: then evaporate at a low temperature and scale. This is a very elegant preparation. The syrup may be formed by adding 3 grains of the above salt to each dram of simple syrup, or it may be flavoured with orange flowers.

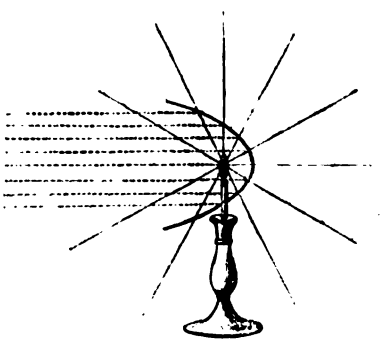
On the Illumination of Lighthouses — The Electric Light, by M. Faraday, *D.C.L., F.R.S., Fullerian Professor of Chemistry, R.I., Foreign Associate of the Academy of Sciences, Paris, &c.*

There is no part of my life which more than my connexion with the Trinity House gives me delight. The occupation of nations joined together to guide the mariner over the sea, to all a point of great interest, is infinitely more so to those who are concerned in the operations which they carry into effect, and it certainly has astonished me since I have been connected with the Trinity House to see how beautifully and how wonderfully shines forth amongst nations at large the desire to do good; and you will not regret having come here to-night, if you follow me in the various attempts which have been made to carry out the great object of guiding in safety all people across the dark and dreary waste of waters. It is wonderful to think how eagerly efforts at improvement are made by the various public bodies — the Trinity House in this country, and commissions in France and other nations; and whilst the improvements progress we come to the knowledge of such curious difficulties and such odd modes of getting over those difficulties as are not easy to be conceived. I must ask you this evening to follow me from the simplest possible method of giving a sign by means of a light to persons at a distance, to the modes at which we have arrived in the present day; and to consider the difficulties which arise when carrying out these improvements to a practical result, and the extraordinary care which those who have to judge on these points must take in order to guard against the too hasty adoption of some fancied improvement, thus, as has happened in some few cases, doing harm instead of good.

If I try to make you understand these things partly by old models, and partly by those which we have here, it is only that I may the better be enabled to illustrate that which I look forward to as the higher mode of lighting, by means of the electric lamp and the lime light.

There is nothing more simple than a candle being set down in a cottage window to guide a husband to his home, but when we want to make a similar guide on a large scale, not merely over a river or over a moor, but over large expanses of sea, how can we then make the signal using only a candle? I have shown in this diagram (*fig.* 1.) what we may

Fig. 1.

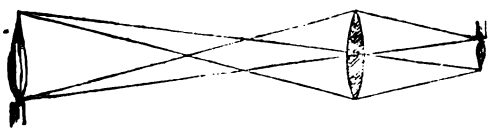


imagine to be the rays of a candle or any other source of light emanating from the centre of a sphere in all directions round to infinite distances. After this simple kind of light had been used for some time, it being found to be liable to be obscured by fogs, or distance, or other circumstance, there arose the attempt to make larger lights by means of fires; and after that there was introduced a very important refinement in the mode of dealing with the light, namely the principle of reflection; — for understand this (which is not known by all, and not known by many who should know it), that when we take a source of light, a single candle, for instance, giving off any quantity of light, we can by no means increase that light: we can make arrangements around and about the light, as you see here, but we can by no means *increase the quantity* of light. The utmost I can do is to *direct* the light which the lamp gives me by taking a certain portion of the rays going off on one side and reflecting them on to the course of the rays which issue in the opposite direction. First of all, let us consider how we may gather in the rays of light which pass off from this candle. You will easily see that if I could take the half rays on the one side and could send them by any contrivance over to the other side, I should gain an advantage in light on the side to which

I directed them. This is effected in a beautiful manner, by the parabolic mirror, by means of which I gather all that portion of the rays which are included in it; upwards, downwards, sideways, anywhere within its sphere of action; they are all picked up and sent forward. You thus see what a beautiful and important invention is that of the parabolic reflector for throwing forward the rays of light.

Before I go further into the subject of reflection let me point out a further mode of dealing with the direction of the light. For instance, here is a candle, and I can employ the principle of *refraction* to bend and direct the rays of light, and if I want to increase the light in any one direction I must either take a reflector or use the principle of refraction. I will place this lens (*fig.* 2.) in front of the candle and you

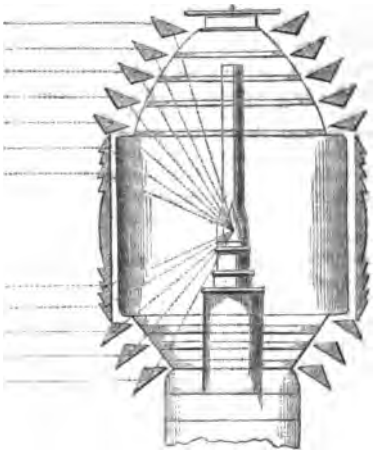
Fig. 2.



will easily see that by its means I can throw on to that sheet of paper a great light, that is to say, that instead of the light being thrown all about, it is *refracted* and concentrated on to that paper; so here I have another means of bending the light and sending it in one direction; and you see above a still better arrangement for the same purpose,—one which comes up to the maximum, I may say, of the ability of directing light by this means. You are aware that without that arrangement of glass the light would be dispersed in all directions, but the lens being there, all the light which passes through it is thrown into parallel beams and cast horizontally along. There is consequently no loss of light, the beam goes forward of the same dimensions, and will consequently continue to go forward for 5 or 10 miles, or so long as the imperfection of the atmosphere does not absorb it; and see! What a glorious power that is, to be able to convert what was just now darkness on that paper into brilliant light.

Whenever we have refraction of this sort we are liable to an evil consequent upon the necessary imperfections in the form of the lens; and Dr. Tyndall will take this lens, and will show you even in this small and perfect apparatus what is the evil of spherical aberration with which we have to fight. This can be illustrated by means of the electric lamp; if you look at the screen, you will see produced, by means of this lens, a figure of the coal points. This image is produced by the rays which pass through the *middle* of the lens, a piece of card with a hole in the centre being placed in front; but if, keeping the rest of the apparatus in the same position, I change this card for another piece which will only allow the rays to pass through the *edge* of the lens, you observe how inferior the image will be. In order to get it distinct I have to bring the screen much nearer the lamp; and so if I take the card away altogether, and allow the light to pass through all parts of the lens, we cannot get a perfect image, because the different parts of the lens are not able to act together. This spherical aberration is, therefore, what we try to avoid by building up compound lenses in the manner here shown. (*fig.* 4.) Look at this beautiful apparatus, is it not a most charming piece of workmanship? Buffon first and Fresnel afterwards, built up these kinds of lenses, ring within ring, each at its proper adjustment, to compensate for the effects of spherical aberration; the ring round that centre lens is ground so as to obviate what would otherwise give rise to spherical aberration, and the next ring being corrected in the same manner, you will perceive, if you look at the disc of light thrown by the apparatus upstairs, that there is nothing like the amount of aberration that there would have been if it had been one great bulls-eye. Here is one of Fresnel's lamps of the fourth order so constructed (*fig.* 3.): observe the fine effect obtained by these different lenses as you see them revolve before you, and understand that all this upper part is made to form part of the lens, each prism throwing its rays to increase the effect, and, although you may think it is imperfect because if you

Fig. 3.



happen to sit below or above the horizontal line, you perceive but little if any of the light, yet you must bear in mind that we want the rays to go in a straight line to the horizon. So that all that building up of rings of glass is for the purpose of producing one fine and glorious lens of a large size, to send the rays all in one direction. Here is another apparatus used to pull the rays down to a horizontal sheet of light, so that the mariner may see it as a constant and uniform fixed light; the former lamp is a revolving one, and the light is seen only at certain times as the lenses move round, and these are the points which make them valuable in their application.

There are various orders and sizes of lights in lighthouses to shine for twenty or thirty miles over the sea, and to give indications according to the purposes for which they are required; but suppose we want more effect than is produced by these means, how are we to get more light? Here comes the difficulty. We cannot get more light, because we are limited by the condition of the burner. In any of these cases, if the spreading of the ray, or *divergence* as it is called, is not restrained, it soon fails from weakness, and if it does not diverge at all, it makes the light so small, that perhaps only one in a hundred can see it at the same time. The North Foreland lighthouse is, I think, 3 or 400 feet above the level of the sea, and therefore it is necessary to have a certain divergence of the beam of light in order that it may shine along the sea to the horizon. I have drawn here two wedges, one has an angle of 15°, and shows you the manner in which the light opens out from this reflector seen at the distance of half a mile or more, the other wedge has an angle of 6°, which is the beautiful angle of Fresnel. When the angle is less than 6°, the mariner is not quite sure that he will see the light—he may be beneath or above it; and in practice it is found that we cannot have a larger angle than 15°, or a less one than 6°. In order therefore to get more light, we must have more combustion, more cotton, more oil; but already there are in that lamp four wicks put in concentric rings, one within the other, and we cannot increase them much more, owing to the divergence which would be caused by an increase in the size of the light—the more the divergence, the more the light is diffused and lost. We are therefore restrained by the condition of the light and the apparatus to a certain sized lamp. At Teignmouth, some of the revolving lights have ten lamps and reflectors, all throwing their light forward at once. But even with ten lamps and reflectors we do not get sufficient light, and we want therefore a means of getting a light more intense than a candle in the space of a candle—not merely an accumulation of candle upon candle, but a

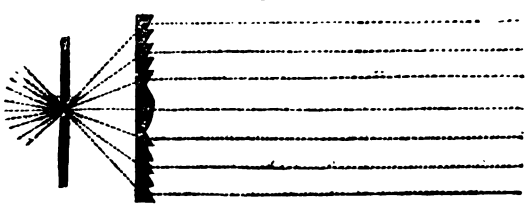
concentration into the space of a candle, of a greater amount of light, and it is here that the electric light comes to be of so much value.

Let me now show you what are the properties of that light which make it useful for lighthouse illumination, and which has been brought to a practical condition by the energy and constancy of Professor Holmes. I will first of all show you the image of the charcoal points on the screen, and draw your attention to the spot where the light is produced. There are the coal points. The two carbons are brought within a certain distance; the electricity is being urged across by the voltaic battery, and the coal points are brought into an intense state of ignition. You will observe that the light is essentially given by the carbons; you see that one is much more luminous than the other, and that is the end which principally forms the spark, the other does not shine so much, and there is a space between the two which, although not very luminous, is most important to the production of the light. Dr. Tyndall will help me in showing you that a blast of wind will blow out that light; the electric light can in fact be blown out easier than a candle. We have the power of getting our light where we please; if I cause the electricity to pass between carbon and mercury I get a most intense and beautiful light most of it being given off from the portion of the mercury between the liquid and the solid pole. I can show you that the light is sometimes produced by the vapour betweent he two poles, better if I take silver than when I use mercury. Here is the carbon pole, there is the silver, and there is the beautiful green light which comes from the intervening portions. Now that light is more easily blown out than the common lamp, the slightest puff of wind being sufficient to extinguish it, as you will see if Dr. Tyndall breathes upon it.

You see, therefore, how we are able, by using this electric spark, to get, first of all, the light into a very small space. That oil lamp has a burner $3\frac{3}{4}$ inches in diameter; compare the size of the flame with the space occupied by this electric light. Next compare the intensity of this light with any other; if I take this candle and place it by the side, I actually seem to put out the candle. We are thus able to get a light which, while it surpasses all others in brilliancy, is at the same time not too large, for I might put this light into an apparatus not larger than a hat, and yet I could count upon the rays being useful. Moreover, when such large burners are used in a lantern, we have to consider whether the bars of the window do not interfere to throw a shadow or otherwise; but with this light there will be no difficulty of that sort, as a single small speculum no larger than a hat will send it in any direction we please; and it is wonderful what advantages, by reason of its small bulk, we have in the consideration of the different kinds of apparatus required, reflecting or refracting, irrespective of other reasons for using the electric light. And it is these kind of things which make us decide most earnestly and carefully in favour of the electric light.

I am going to show you the effect that will take place with that large lens when we throw the oil lamp out of action, and put the electric light into use. It is astonishing to find how little the eye can compare the relative intensities of two lights; look at that screen and try to recollect the amount

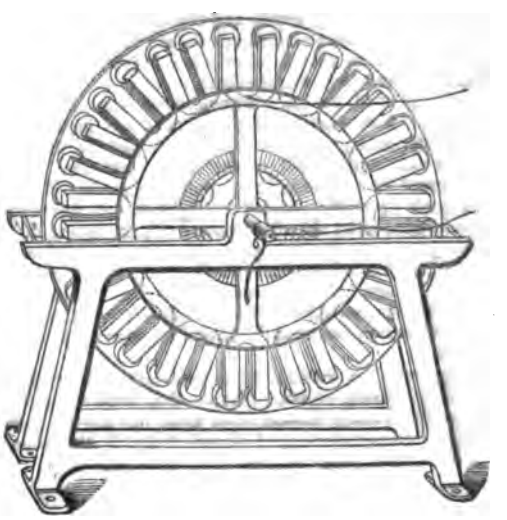
Fig. 4.



of light thrown upon it from the $3\frac{3}{4}$ inch lamp of Fresnel, and now, when we shift the lens sideways, look at the glorious light arising from that small carbon point (*fig.* 4.); see how beautifully it shines in the focus of that lens and throws the rays forward. At present the electric light is put at just the same distance as the oil light, and therefore, being in the focus of the lens, we have parallel rays which are thrown forward in a perfectly straight line, as you will see by comparing the size of the lens with that of the light thrown on the screen. You will now see how far we can affect this beam of light by increasing or diminishing the distance of the lamp. We are able by a small adjustment to get a beam of a large or small angle, and observe what power I have now over it; for if I want to increase the degrees of divergence, I am limited by the power of light in the case of the oil lamp, but with the electric light, I can make it spread over any width of the horizon by this simple adjustment. These then are some of the reasons which make it desirable to employ the electric light.

By means of a magnet, and of motion, we can get the same kind of electricity as I have here from the battery; and under the authority of the Trinity House, Professor Holmes has been occupied in introducing the magneto-electric light in the lighthouse at the North Foreland; for the voltaic battery has been tried under every conceivable circumstance, and I take the liberty of saying it has hitherto proved a decided failure. Here, however, is an instrument wrought only by mechanical motion. The moment we give motion to this soft iron in front of the magnet, we get a spark. It is true in this apparatus it is very small, but it is sufficient for you to judge of its character. It is the *magneto-electric* light, and an instrument has been constructed as there shown (*fig.* 5.)

Fig. 5.



which represents a number of magnets placed radially upon a wheel — three wheels of magnets and two sets of helices. When the machine, which is worked by a two-horse power engine, is properly set in motion, and the different currents are all brought together, and thrown by Professor Holmes up into the lantern, we have a light equal to the one we have been using this evening. For the last six months the North Foreland has been shining by means of this electric light — beyond all comparison better than its former light. It has shone into France, and has been seen there and taken notice of by the authorities, who work with beautiful accord with us in all these matters. Never for once during six months has it failed in doing its duty; — never once, more than was expected by the inventor. It has shone forth with its own peculiar character, and this even with the old apparatus —for as yet no attempt has been made to construct special reflectors or refractors for it, because it is not yet established.

I will not tell you that the problem of employing the magneto-electric spark for lighthouse illumination is quite solved yet, although I desire it should be established most earnestly (for I regard this magnetic spark as one of my own offspring). The thing is not yet decidedly accomplished, and what the considerations of expense and other matters may be, I cannot tell. I am only here to tell you as a philosopher, how far the results have been carried, but I do hope that the authorities will find it a proper thing to carry out in full. If it cannot be introduced at all the lighthouses, if it can only be used at one, why really it will be an honour to the nation which can originate such an improvement as this,—one which must of necessity be followed by other nations.

You may ask, what is the use of this bright light? It would not be useful to us were it not for the constant changes which are taking place in the atmosphere, which is never pure. Even when we can see the stars clearly on a bright night it is not a pure atmosphere. The light of a lighthouse, more than any other, is liable to be dimmed by vapours and fogs, and where we most want this great power, is not in the finest condition of the atmosphere, but when the mariner is in danger, when the sleet and rain are falling, and the fogs arise, and the winds are blowing, and he is nearing coasts where the water is shallow and abounds with rocks—then is his time of danger, when he most wants this light. I am going to show you how, by means of a little steam, I can completely obscure this glorious sun, this electric light which you see. The cloud now obscuring the light on the screen is only such a cloud as you see when sitting in a train on a fine summer's day; you may observe that the vapour, passing out of the funnel, casts as deep a shadow on the ground as the black funnel; the very sun itself is extinguished by the steam from the funnel, so that it cannot give any light; and the sun itself if set in the lighthouse would not be able to penetrate such a vapour.

Now the haze of this cloud of steam is just what we have to overcome, and the electric light is as soon, proportionally, extinguished by an obstruction of this kind as any other light. If we take two lights, one four times the intensity of the other, and we extinguish half of one by a vapour, we extinguish half of the other, and that is a fact which cannot be set aside by any arrangement. But then we fall back upon the *amount* of light which the electric spark does give us in aid of the power of penetrating the fog, for the light of the electric spark shines so far at times, that even before it has arisen above the horizon twenty-five miles off, it can be seen. This intense light has therefore that power which we can take advantage of,—of bearing a great deal of obstruction before it is entirely obscured by fogs or otherwise.

Taking care that we do not lead our authorities into error by the advice given, we hope that we shall soon be able to recommend the Trinity House, from what has passed, to establish either one or more good electric lights in this country.

PHARMACEUTICAL SOCIETY, 7 *March* 1860.

(*Continued from p.* 161.)

Dr. Redwood made a verbal communication *On the Composition of Hydrargyrum cum Cretâ.* He said that in a former communication he had stated the results of his experiments, undertaken to ascertain whether arsenic or antimony was ever contained in Hydrargyrum cum Cretâ. He had not been able to find either of these substances in any of the specimens he had examined. In the course of the investigation, however, another and very important question had been suggested, viz. "What is the real nature and composition of Hydrargyrum cum Creta?" It is always said to be a mixture of chalk and finely-divided mercury, with sometimes a small proportion of protoxide of mercury; but in no publication is the amount of the last said to be more than a fraction of a grain per cent. Dr. Nevins had found rather more than one half per cent. and others had arrived at the same result. In his previous communication Dr. Redwood had stated his belief that the more violent and prolonged trituration to which the mercury was subjected in the preparation of grey powder by machinery most probably resulted in the formation of a much larger amount of the protoxide, which he thought would account for the dangerous symptoms at times produced by the medicine. The analysis of several specimens had shown that this was really the fact. On treating these specimens with acetic acid he had found that the filtered liquor contained abundance of acetate of the protoxide. But in the course of the investigations a still more important matter had been revealed—the presence of a considerable proportion of the peroxide of mercury. The analyses showed, in fact, that the preparation had no uniform composition. That it might sometimes be a mild and at other times a dangerously active medicine. According to Pereira the protoxide of mercury is the least irritating of mercurial preparations, never producing disorder in the intestinal canal; but the peroxide is a powerful irritant. The effects of Hydrargyrum cum Cretâ, then, depend on the presence of these two oxides. If only protoxide be present the action will probably be mild; but if it contain peroxide it may be dangerously active. In order to discover what was the real composition, a number of samples had been submitted to analysis, and the results of some will be found in the following table:

	Hg.	HgO.	HgO_2
1.	37·1	0·4	trace
2.	32·5	3·74	1·45
3.	27·9	4·99	5·18
4.	20·4	13·1	4·86
5.	21·7	7·9	8·85
6.	13·1	11·64	14·25

The sample No. 1 was made by rubbing the mercury and chalk together in a pestle and mortar, which was the proper way of preparing the medicine.

The methods used for determining the amount of the two oxides were as follows:—The specimens were first treated with warm dilute hydrochloric acid, which dissolved the peroxide, forming corrosive sublimate, and converted the protoxide into calomel, which was left behind with the metallic mercury. The amount of peroxide was obtained from the bichloride in solution. The amount of protoxide could be calculated from the chloride left after dissolving the metallic mercury with dilute nitric acid; but in these cases another plan had been adopted. A separate portion of the Hydrargyrum cum Cretâ was treated with hydrocyanic acid, which converted the whole of the peroxide and half the protoxide into cyanide, and left the other half of the protoxide behind in the form of metallic mercury. The difference obtained by subtracting the weight of peroxide obtained from the bichloride and that obtained from the cyanide calculated into protoxide and multiplied by two, would of course give the amount of the whole of the protoxide contained in the specimen.

A reference to the table will show how different was the composition of the samples examined. No 1 was a harmless preparation; but No. 6 was poisonous. How was the presence of this large amount of the peroxide to be accounted for? In the first place it could not be doubted that by the use of the steam engine, the action of which was continued for days, a large quantity of protoxide was formed. If it remained in this state the medicine would still be harmless. But, unfortunately, if safe and mild when first prepared, it cannot be kept so: for by the action of light the protoxide is converted into the peroxide and metallic mercury, and thus a dangerous ingredient, never intended to form part of it is introduced into the preparation. In Pilula Hydrargyri no protoxide could be discovered—the mercury being protected from oxidation by the saccharine matter of the confection; and probably the best method of preparing the Hyd. c. Cret. would be that of the Dublin Pharmacopœia, which orders the mercury to be first triturated with manna before it is rubbed with the chalk. The efficacy of the medicine probably does not depend on the protoxide. We have no

chemical evidence that anything more than mercury in a fine state of division is to be found in blue pill, and yet it is known to be an active mercurial.

Dr. Redwood intends to make further investigations before the next meeting, when the subject will be fully discussed.

The Chairman said the subject was one of great importance to the medical profession. Dr. Redwood's experiments went to show that a medicine in great repute was no longer the same it used to be. Although greatly changed in composition, but slight alteration took place in the appearance, and that could only be detected by the use of the microscope.

The meeting then adjourned.

SOCIETY OF ARTS, *Wednesday, 7 March* 1860.

J. Bennet Eames, *Esq., F. R. S. in the Chair.*

At this meeting Mr. Alderman Mechi read a paper *On the Application of Town Sewage to Agriculture*, but we do not think that a detailed account of the proceedings would either interest or instruct our readers, the paper itself being little more than a statistical catechism of farm operations, together with copious extracts from the opinions and writings of Mr. Eames, Dr. Voelcker, and others. Mr. Mechi advocated a complete system of inland irrigation with the *liquid manure* of towns, and endeavoured to prove that the latter contains the necessary elements in a far more concentrated state than other matters usually employed for the purpose, and diluted by rain—an ingenious, but somewhat unfortunate idea. The bitumenised paper pipes of Messrs. Jaloureau & Co. of Paris (Chemical News, p. 120) were exhibited and noticed as well adapted for both the fixed and "travelling" irrigation recommended in the paper.

In the discussion which followed the reading of the paper, some of the most diverse opinions were put forth by various speakers, but few however possessing any practical character. Mr. Mechi was on the whole well supported by Messrs. Robert Rawlinson and P. H. Holland who corrected some erroneous assertions of Mr. Sidney and other speakers. We will give one instance, a rather amusing one: Mr. Holland said—"he would, in conclusion, only allude to the fallacy which Mr. Sidney had put forth upon the authority of Mr. Hawksley; that gentlemen, an engineer, had put forward a notion which must be astounding to every chemist. It was this—'*that if sewage ran away for a distance of about* 10 *miles, it was no longer sewage, but almost plain water.*'" The readers of the Chemical News will probably agree with Mr. Holland on this point. Without agreeing in detail with Mr. Mechi, we think his paper will do good, and regret that the form in which it appears is not very well adapted for general circulation; but those who are interested in the question of the extended application of sewage, may study it at length in the *Journal of the Society of Arts*.

Mr. Mechi is evidently too sanguine in his views and expectations, but ridicule can only be successfully met in this way, and a little extra enthusiasm often does a world of good.

NOTICES OF BOOKS, PATENTS, &c.

Experimental Researches in Chemistry and Physics, by Michael Faraday, *D. C. L., F. R. S., &c. &c. &c.* London: Taylor & Francis. 1859.

We once thought that there was something terrible in the idea of the unsympathising nature of matter. But we almost begin to think that there are some in whom the promise has been fulfilled that they "shall be in league with the stones of the field." To those who earnestly love matter, not *as* matter, but as a storehouse of wondrous forces, as a fountain from which unfailing draughts of sweet knowledge may be drunk by the nature seeking; matter is not unsympathising. Nature is well represented as a woman, for not only does she bestow her favours capriciously and unequally among her worshippers, but those upon whom she smiles are generally jealous of their fellow-devotees. Of all jealousies this surely is the least evil, only those who worship nature and seek her with untiring zeal can know the sadness of only receiving an occasional, and perhaps faint smile. Her smiles are discoveries.

It is very interesting and instructive to observe how those who have penetrated furthest within the veil, those who have accumulated the greatest number of facts, avoid dogmatic theorising. Far be it from us to despise theories or their inventors, the discovery of facts necessitates the construction of theories to connect them, and enable us to push on in hope of accumulating more. The great man whose discoveries now lie before us is a most instructive example of the fertile discoverer and the cautious reasoner. Ever since the time when providence placed him in the laboratory where he has almost unceasingly worked, he has given to the world at intervals of varying duration the results of his researches, and there has perhaps never been a philosopher whose results have been so uniformly accurate. His constant succession of discoveries has placed him in so elevated a rank in science that any theoretical [assertions he might utter, would by a vast number of his admirers be received with implicit faith. This, in most men's hands would be a dangerous power to wield; but happily for the progress of science in this country, the power has scarcely been used, never abused. Every one knows that in France there has always, from the time of Lavoisier, ay, and even before that, been an authority in science as in politics, who has exercised despotic sway. If any man in this country has had the power of taking this position that man has been Faraday; but content with gleaning rich harvests of facts from the ripe fields of chemistry and physics, and with expounding those facts to the world, he has confined himself to his mission. And a glorious mission it has been; we can conceive no higher, no happier destiny on this earth than the successful study of the wondrous and wondrously beautiful properties of matter. It is impossible to read his works without instantly catching the spirit of enthusiasm which breathes in every page. This appears to be one of the great secrets of his success as a lecturer, he so intensely enjoys the outward signs of the concealed forces that his enjoyment is communicated to his audience. They see with him that "the glorious spark" is but a manifestation of those intense energies which, pervading all matter, have been evoked to do man's bidding, and although his servants, as being at his command, are his masters from the manner in which they influence his destiny.

The work before us opens with a paper which will, while the scientific literature of this country lasts, be read with a high degree of interest. Not that it is especially remarkable for scientific accuracy as an analytical work, or even from the somewhat curious fact it for the first time announces, but as being the paper which introduced Faraday to the world. It is an "Analysis of Native Caustic Lime." The next paper is valuable as opening up a subject which has, in the hands of Graham and Bunsen led to results of great importance; it is "On the Escape of Gases through Capillary Tubes." We pass over a number of communications, each, however, containing matter at the time of high interest, and proceed to his paper "On Two New Compounds of Chlorine and Carbon, and on a New Compound of Iodine, Carbon, and Hydrogen." Almost at the commencement of this research the fact is stated that the oil of olefiant gas is formed by the union of equal volumes of chlorine and the hydrocarbons. In these days when the action of the halogens upon organic bodies has been studied so minutely, we are liable to look over the importance of an experiment demonstrating that four volumes of chlorine and four volumes of olefiant gas united to form the oil of the Dutch chemists. We then have the results of his examination of the action of free chlorine and sunlight upon the oil, the final result being the important discovery of the sesquichloride of carbon. It

is true that it was reserved for more recent researches to ascertain the successive steps of substitution by which the compound is produced. Faraday, from his analysis, therefore deduced C_2Cl_2 as the simplest formula consistent with whole atoms. We now know that the formula must be written C_4Cl_6. We next have the discovery of the protochloride of carbon, and, as with the last, Faraday wrote the formula in the simplest manner, namely CCl; now we know from the mode of derivation, and more especially from its vapour density (5·82), that the above formula must be multiplied by four to give the true formula, which has a theoretical vapour density of 5·81.

Passing over the papers which intervene, we at once spring to the beautiful researches upon the liquefaction of the gases. The whole of the papers upon this subject are models, not only as to the mode in which researches should be carried out, but for the exquisite candour and fairness with which the results of others are given. Now that gases are generally acknowledged to be merely the vapours of intensely volatile liquids, we are apt to forget the freshness and novelty which the scientific public found in the subject. Philosophers, even including our author, began at once to speculate upon the liquefaction, and even solidification, of the two great archetypal gases, oxygen and hydrogen. As yet we have not had a realisation of this great problem, but, undoubtedly, it will one day be done by an extension of the same principal as that by which successful results were obtained with other gases. Every one is aware of the analogy of hydrogen to metals, that is to say, that in the types of water, ammonia, ammonium, and hydrogen (HH), metals and two volumes of hydrogen can be made to replace each other to an almost unlimited extent. It was this which led Dumas to believe that solidified hydrogen would resemble a metal in appearance. This, however, is a very unnecessary speculation, inasmuch as metallic lustre is not a character of great philosophical importance, and it is quite as likely that solidified hydrogen may be a transparent colourless solid.

We shall allude to only one more subject, namely, the experiments on the preparation of silicated borate of lead or heavy glass. This glass has now acquired almost sacred interest, owing to the fact of its having been the substance used by Faraday in his experiments on the illumination of the magnetic lines of force.

Of Faraday as chemist, physicist and philosopher it is difficult to speak analytically. It may indeed be said of him as of poor Goldsmith (and in a far higher sense) that he has left nothing untouched, and touched nothing without adorning it. If there be any true line of demarcation between chemistry and physics, if therefore we can speak separately of Faraday as a chemist and physicist, we should say that he was *one* of the most brilliant chemists and *the* most brilliant physicist the world has as yet seen, — shall we ever see a greater?

Improvements in the Manufacture of Gas. William Knapton and Adam Aitchison.

The inventors subject to dry distillation the refuse bark of tan pits or the bark of trees, wood of all kinds, in fact, and collect the gas evolved, which they say is "a pure hydrogen gas" with nearly the same illuminating power as coal gas, but without its unpleasant smell. In order to give the gas produced the greatest illuminating power they pass it over or through naphtha or camphine when it will give out a more brilliant light than coal gas. The inventors claim as their invention the manufacture of gas from all sorts of timber refuse. The patentees say nothing about the purification of the gas, but our readers will remember a communication from Mr. Proctor in our last number (p. 155) relative to the use of the spent bark of tanneries, in which that gentleman says it is necessary to pass the gas through milk of lime — a necessity which of course any chemist would have recognised.

Improvements in treating Ores to obtain a new Metallic Substance and its Salts, and in the application of such Matters, and also certain Products of Tungsten in Dyeing, Printing, and Painting. F. W. Emerson.

This consists: 1. In the separation of a metallic substance, which the inventor designates "chrolithineum," from wolfram, tungstate of lime, tungstic oxide, and other ores of tungsten, and in the manufacture and application of its various salts to dyeing textile fabrics, painting on porcelain, and the production of paints and pigments. 2. In the manufacture and application of the blue oxide of tungsten as a dyeing substance for textile fabrics, and as a paint or pigment. 3. In the production of paratungstate of alkali, metatungstate of alkali, isotungstate of alkali, and polytungstate of alkali, which may be used in the preparation of paints and pigments, and for dyeing textile fabrics, and for other purposes, and in the combination of paratungstic, metatungstic, isotungstic, and polystungstic acids with any suitable metallic oxide or mixtures of metallic oxides as a base, such as the oxides of lead, zinc, barytes, lime and others, to form paints and pigments.

Powder or Mixture for Refining and Steelifying Iron. (A communication.) R. A. Brooman.

The important part that carbon plays in the conversion of iron into steel is at the bottom of all existing modes of operating, and the inventor of this process fancies that he has discovered a new means of fixing this element in its purest and most convenient form. Accordingly he exposes quick lime to the atmosphere to absorb carbonic acid and to be made use of in the manner we shall presently see. The inventor further states that it is a well known fact that the Danemora iron of Sweden, which furnishes the best steel, contains a notable quantity of phosphorus to such an extent indeed that when bent or twisted at a dull red heat, it gives out a strong odour of phosphorus. From this and other facts Brande and other practical chemists maintain that the presence of phosphorus is essential to the production of first-rate steel, and the inventor's own experience leads him to the same conclusion. So with a view of adding phosphorus to the iron, bone dust is used. The powder which is patented is composed of equal parts of caustic lime, bone dust and charcoal, oak being preferred. These are mixed together and then exposed to the air for two or three days in dry weather. The iron to be operated on is placed with the powder in a cementing or converting furnace, which is then luted up, and heat is applied, and maintained at an equable and not too elevated temperature. By this means the inventor is enabled to give iron entirely new properties and qualities, as well as to convert it or partially convert it into steel at pleasure. Iron treated in this way assumes great rigidity and hardness without losing its properties of malleability and ductility. Any articles large or small may be finished in iron and then converted or partially converted into steel without impairing their forms. The process also gives iron the property of resisting oxidation in a high degree.

CORRESPONDENCE.

Nutritive Properties of Aluminised Bread Food.

To the Editor of the Chemical News.

Sir, — In reply to a letter in your journal of March 3, will you allow me to say that it is scarcely to be expected that I should reply to anonymous correspondents, however kindly and courteously the queries are put. Remarks besides made at a public meeting, and necessarily reported in abstract, can after all only convey a very inadequate account of what was said. I will however on this occasion endeavour to reply to Common Sense, but must altogether decline a paper war.

The statement that alum renders bread indigestible and forms an insoluble salt with phosphoric acid is given on the authority of Liebig. I am therefore content to leave Common Sense to fight his battle with that distinguished German chemist. Still I may say that as all admit that a certain amount of free acid and phosphates is essential to the metamorphosis of tissue, it is chiefly the free phosphoric acid which is taken up by the alum, and thus in great measure lost to the system; and we learn from Erdmann's analysis of the ashes of wheat, deducting 1·33 of peroxide of iron, and 33·7 of silica or sand per cent. that there exists in 100 parts (Liebig):

Alkaline phosphates (PO_5MO)	49·18
Earthy ditto (PO_52MO)	23·13
Free phosphoric acid	27·69

Now as from a mean of seven experiments 100 parts of wheat flour contain 1·83 of salts, 1 lb. of flour would contain 128 grs. of salts, 34·3 grs. only would be free phosphoric acid. The amount of phosphoric acid thus converted into phosphate of alumina would vary according to the amount of alum used, and this, I believe (if the bread be made with musty or inferior flours, no uncommon event in large towns), would far exceed 2 oz. in 56 lbs.

Moreover the so said solubility of phosphates of alumina in organic matters of digestion (even if true for adults) remains to be proved for infants. Certain it is many infants become thin, pale, emaciated, on aluminised bread, while they thrive on home-baked bread which contains no alum. Dr. Hassall moreover has proved that nearly all the London bakers' bread does contain alum. Now facts are stubborn things.

Secondly, the appearance of an atrophied child is not unlike that of an opium eater. If Common Sense has ever seen a child habitually drugged with opium by an unprincipled nurse, he will have found the resemblance between such a child and one poisoned by aluminised bread to be very great. The march of symptoms differs, but the result upon the frame is very similar in both cases. So far it is true alum is as sure a poison as opium, if long persisted in. Both hasten death by atrophe.

What I stated in my remarks at the Hanover Square Rooms was that "chloride of potassium, at any rate, potash salts," were essential in cell growth. On the latter point the latest German writers agree. That the potash salt is the chloride of potassium is *my* belief; but I do not wish to anticipate here views not yet complete, but which I hope ere long to publish. Whatever takes place however in the vegetable kingdom in regard to the natural substitution of chlorides of potassium and sodium certainly does not as invariably hold good in the animal kingdom. It is not by accident that so much chloride of potassium is found in muscle and its juices, and so little of chloride of sodium; and so much of the latter salt and so little of the former in the blood. Again, although in an adult it may be reasonable to admit that it is equally advantageous to supply a potash salt as a chloride, phosphate, or sulphate; yet, as in milk, *the* food *par excellence* for a babe, potash is supplied only as a chloride, the fact implies an advantage if not a necessity for this, although as yet we may not be able to explain the reason.—I am, &c.

C. H. F. Routh, M.D.

Observations upon the Phenomena of Heat and Sound, with reasons for supposing them identical both in nature and operation.

To the Editor of the Chemical News.

Sir,—In commencing any physical inquiry, one of the first things to be noticed is, that law declared by Newton with reference to the adequate, and not more than adequate, conception of cause with relation to effect. We should never receive into our idea of cause anything which does not appear necessary to explain the effect produced. I apprehend that this precept has been greatly overlooked, and that the phenomena about to be noticed present striking examples of this. It is true that they are of a nature which apparently renders their investigation most difficult. Nevertheless, I think that the want of success which has characterised the labours of others who have studied them, has greatly helped to make the interpretation of these phenomena appear more difficult than is really the case. I remark that our knowledge of all such phenomena has been overrated. Philosophers assuming connection where none can be proved to exist, or fancying complication of effect, both being with a view to render phenomena explicable. As regards heat, everyone is aware that the term expresses something, our conception of which is indefinite; that is of the phenomenon itself, as separated from our sensation of it, or its effect. If we suppose that heat is something apart from the sensation of the friction of some substance, I apprehend that we go farther than ascertained and universally acknowledged facts will carry us. Let us see what is the utmost we know concerning this phenomenon. It is found that in various ways we become acquainted with the sensation termed heat, but I think that in no case have we evidence of the presence of any new substance. Under ordinary circumstances the friction of the atmosphere appears to me sufficient to account for every manifestation of heat. The hypothesis which considers heat as motion among the particles of bodies, appears to me capable of explaining the change of water into steam and ice. This action may cause the particles of water mutually to repel each other in the case of steam, which friction, growing dead, may cause water to assume that condition known as ice. The production of heat by friction appears to me to afford a very strong argument in favour of this hypothesis, especially as frictional heat has been produced in an exhausted receiver. The fact of heat having traversed the Torricellian vacuum proves that the friction of the atmosphere does not cause it, but I submit that this does not *per se* establish the existence of a new element. I think that the vibrations of some element which cannot be disposed of in the same way as air may affect the enclosed thermometer; and that it is as probable that this is the case as that the so-called heat is produced. From an experiment of Sir H. Davy, it appears that in a considerably attenuated atmosphere, the heat caused by a piece of platinum wire, charged with voltaic electricity, was three times as great as it was in air of the natural density. This proves that the atmosphere in its ordinary state is unfavourable to its production, but I do not think that it renders probable the hypothesis of a calorific fluid. The attempts to discover whether the application of heat to bodies affects their weight, being of a nature very liable to mistake, and contradictory results having been obtained, it is perhaps best to pass over this consideration; although, if satisfactorily investigated, the conclusion found must evidently be final. The experiment of Berthollet with various metals, proving that their latent heat decreased with their pressure, seems to prove the hypothesis of motion among the particles of bodies. It is natural to suppose that the more bodies are compressed, the less motion will there be among their particles; and consequently, their friction upon the atmosphere or any substance with which they may come in contact will decrease; and its sensation, which we name heat. I think, then, that until some philosopher shall produce a solid reason for supposing the creation of heat, more probable than the hypothesis concerning the friction of some elements, more ethereal than the most attenuated atmosphere, and existing both with it and where this does not, they cannot philosophically assume its presenee.

That the atmosphere, along with every other body, conducts sound, every one admits, although there may be differences as to the conception of the cause of this sensation. Because a bell will not sound in a very attenuated atmosphere, it is concluded that air is necessary for the transmission of sound; and here it appears to me that we have an

example of the error of complicating effects, although it is difficult to see how this renders the phenomenon more intelligible. I apprehend that it has never been demonstrated that the friction of the atmosphere upon the ear is not that which we term sound; and certainly something should be adduced in opposition to this most natural idea, before it is assumed that something is created whenever sound is heard. A bell will not sound in a very attenuated atmosphere because its friction is lost upon it: the medium is too subtle to convey the vibrations in the form of undulations to the receiver, and hence the external atmosphere cannot become affected, and thereby convey to the ear the friction known as sound. There does not here appear to me any necessity for supposing the creation, using the term as before in a generalised sense, of anything, and I cannot think of any phenomena where this hypothesis is in any wise requisite. If the bell is connected with a rod projecting through the top of the receiver, I think I correctly say that its sound will be audible to an ear placed close to the rod. The friction may pass directly from the rod, or affect the atmosphere, and the ear at a little distance.

Thus it appears to me that heat and sound are identical in nature. The consideration of sound being but a name for a sensation, and heat the undulations of some subtle medium, does not render the two phenomena diverse in nature. The one appears to me to depend upon our ordinary atmosphere and other media, and the other upon the undulations of some ethereal element which cannot at present be fully proved to exist, as it cannot be got rid of. Upon the supposition with respect to heat, no generation is required. It cannot be said that, in asuming the presence of an ethereal substance, I take a great licence, inasmuch as this hypothesis involves far less unsubstantial particulars than that respecting a calorific fluid; besides which, seeing no reasons for considering generation with respect to sound, there is from analogy an evidence against supposing it productive of the sensation of heat; and the hypothesis of an ether, from the analogous one respecting the immensity of space being filled with it, does not stand destitute of high probability. Thus the radical nature or constitution of both elements appears the same; and friction being the mode of effect in both cases, as indeed force always produces change, these phenomena are similar in operation.—I am, &c.

J. A. Davies.

Zinc Ore in the form of Oolite.

To the Editor of the Chemical News.

Sir,—I have read with much interest the notice [in a recent number of the Chemical News on *Zinc Ore in the form of Oolite*.

The occurrence of zinc in this form has not, I believe, been recorded as occurring elsewhere than in the neighbourhood of Santander, neither do I recollect any other metal except iron, as "pisolitic ore," taking this form. Many of the mines near Santander produce zinc ores of peculiar structure and composition. I was favoured about eight months since with a small series of specimens from the mines of the Santander Mining Company, and amongst them was a portion of a large stalactite of calamine, containing a large proportion of ZnO. The structure of this stalactite was laminated like the granules mentioned in your notice; the laminæ were easily separated by the finger nail. I see from my note of the analysis that I made, there was a larger quantity of $CaO.CO_2$ than in the granules of which your correspondent made an analysis, as I found as much as 9·63 of this substance.

The other ores I received were chiefly hydrated silicates, and, unlike many of the German or Derbyshire ores, appeared devoid of all traces of cadmium.

Hoping that the writer of the notice will publish any further researches on this subject,—I am, &c.

W. H. T. Allen.

Chemical Nomenclature.

To the Editor of the Chemical News.

Sir,—I have been somewhat surprised to find, from the correspondence upon this subject, that the terms "nitrate of *potassium*," "sulphate of *barium*," &c. are received with so much difficulty. The theory upon which the new formulæ are based is not by any means a recent one, it having been suggested long ago by the sagacity of Davy. Daniell too, and many others, considered nitric and sulphuric acids as the hydrides of salt-radicals, calling them oxynitrion and oxysulphion respectively. The dictional difficulty may be despatched in a few words. "Your Weekly Guest" has proposed "nitratide of potassium" as a suitable term, apparently in ignorance of the fact that several writers have before suggested the termination *aside* for the compounds of all acids ending in *ic*: this certainly has the advantage of euphony at least, which cannot be obtained if a *t* is introduced, but by either of these methods an additional syllable is necessitated, which to my mind would be a disadvantage far outweighing other considerations.

By retaining the old terms, "nitrate," "sulphate," &c. and applying them to the *metal* instead of to the *oxide*, we have at once a concise and accurate arrangement, requiring but a slight mental effort to fall into, for in many instances the nomenclature remains quite unchanged upon this plan, *e.g.* as in "nitrate of copper," "sulphate of zinc," &c. the only alterations required being in those salts where the metallic oxide has a distinctive title of its own. A trifling objection may perhaps be urged against the binary theory when the salts of alkaloids are considered, as sulphate of quinine would have to be written (according to Laurent's version of its composition) $C_{38}H_{24}N_2O.SO_4$, and I am not aware that $C_{38}H_{24}N_2O$ (or perhaps $C_{40}H_{24}N_2O$) has as yet been obtained.—I am, &c.

Wentworth L. Scott.

The Cavendish Society.

To the Editor of the Chemical News.

Sir,—As you were so good as to insert my former letter, may I ask you to publish the financial statement which usually accompanies the Report of the Cavendish Society. I am anxious to see for myself how far this bears out the council in their resolution to publish no more works until *Gmelin's Chemistry* is finished. A careful examination of these statements for a few years past may perhaps enable us to understand better the present position of the Society, and how it was brought into its present condition.—I am, &c.

A Subscriber to the Cavendish Society.

Manchester, March 13.

[The abstract of the Report we published was kindly supplied by the secretary. The entire Report and the balance will no doubt be printed and circulated among the subscribers immediately.—Ed.]

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

On the Colouration of the Salts of Manganese.—M. A. A. Gorgeu has communicated to the Academy of Sciences the results of some investigations into the constitution of the white and rose coloured oxalates of manganese. He has found that they differ essentially in their chemical composition. The rose-coloured salt may be represented by the formula $C_2O_3MnO.3HO$, and the colourless salt by $C_2O_3MnO_2HO$. The affinity for the water of crystallisation is not the same in both salts. The white salt when exposed to the air undergoes no change, but the rose-coloured loses an equivalent of water, and is changed into a white salt $C_2O_3MnO_2HO$. In a vacuum the colourless salt does not lose weight, while the rose salt parts with some of its water, but does not lose its colour and transparency. When dried

in a stove about 95° C. the white salt remains unaltered, but the red parts with $\frac{2}{10}$ of its water, and keeps only a faint rose tint. The author believes that the simultaneous existence of a rose-coloured and white oxalate is not opposed to the hypothesis which attributes a characteristic colouration to the salts of manganese, since the absence of colour in the oxalate with 2HO may result from chemical and physical differences, which exist between it and the rose-coloured salt.[1]

Preparation of Pure Platinum Black.—M. C. Brunner ainé[2] heats in a capsule dry oxalate of iron until the oxalate is completely changed into oxide, which is reduced in a current of hydrogen. The reduced iron is then added by degrees to a dilute and slightly acid solution of chloride of platinum, until the liquid becomes colourless. The precipitate is treated repeatedly with boiling concentrated nitric acid to remove all traces of iron, and is then washed with weak potash and with water. The black powder so obtained, when heated on platinum foil, suddenly becomes red hot, increases in volume, and is changed into spongy platinum. The same transformation takes place when it is moistened with a few drops of alcohol.

II. ORGANIC CHEMISTRY.

Urate of Quinine.—A physician of Bordeaux who had observed that obstinate cases of intermittent fever which were not relieved by large doses of the sulphate of quinine quickly recovered when the patients drank some of their own urine, came to the conclusion that urate of quinine was a valuable medicinal agent—an idea which, according to Dr. Fleury[3], experience has confirmed. The urate is formed by combining 10 parts of rough quinine with 20 parts of uric acid. The quinine is placed in distilled water and boiled for 10 minutes; the uric acid is then added by degrees and the ebullition continued for an hour, during which time the mixture must be frequently stirred, and fresh quantities of distilled water added. The liquid is filtered off and the marc again boiled in more distilled water for 20 minutes longer, and then filtered. The filtrates are united and evaporated to dryness. In this way a salt is obtained of a beautiful yellow colour, sometimes amorphous, but more frequently crystallised in brilliant spangles. Urate of quinine is soluble in boiling or even warm distilled water, and slightly so in cold water. It is said that smaller doses than are given of the sulphate will cure intermittents, and that the exhibition of it is not followed by the same cerebral disturbance.

Action of Tannin on Ether and Water.—M. Luboldt[4] says that tannin loses more or less water when heated on a bath of chloride of zinc according to the manner in which it has been prepared. When obtained by the method of Pelouze, it loses only 10 per cent. of water, but when evaporated from an aqueous solution it loses 12·85 per cent. Thus dried tannin gives up to *absolute* ether from 2 to 3 per cent. of fixed principles composed of a mixture of tannin, gallic acid, ellagic acids, and fatty and resinous substances. These relations are a little changed when water intervenes. At first anhydrous tannin has a great affinity for water, which it seizes upon and then dissolves in its own weight of ether, forming a syrupy liquid which in the process of Pelouze constitutes the inferior layer. On this pure ether has no action, but if enough water be added, the tannin forms a viscous mass with the two liquids. The results varying according to the proportion of water employed, led the author to believe that they might be occasioned by the property which ether and water have of dissolving one in the other. He found in fact that the syrupy liquid only yielded $\frac{1}{10}$ its weight to water saturated with ether. The three layers obtained by treating tannin with ether and water according to the author are—1, the lower, ether dissolved in hydrate of tannic acid; 2, the second, the syrup liquid of hydrate of tannic acid, dissolved in etherated water; and 3, the same composition containing the fatty and resinous matter.

III. CHEMICAL ANALYSIS.

New Process for the Decomposition of Silicates. When silica having a density of 2·2 (see CHEMICAL NEWS, p. 118) is mixed with two or three times its weight of fluoride of ammonium, and the mixture heated in a platinum crucible, the silica is completely volatilised in the state of fluoride. This does not take place so easily with quartz and sand. Rose[5] points out that the fluoride of ammonium may be employed for the decomposition of silicates. It is easily made by saturating hydro-fluoric acid with ammonia. The impure acid, which generally contains some fluoride of silicon, lead, and iron will answer for the purpose. A small quantity of carbonate and hydrosulphuret of ammonia must be added to the solution, which after a time is decanted and evaporated in a platinum crucible. During the evaporation a small piece of carbonate of ammonia must be added from time to time. When the mass becomes pasty it must be stirred with a spatula. When well dried the salt may be kept in vessels of platinum, silver, or gutta-percha.

The silicate must be very finely pulverised, and mixed with six times its weight of the fluoride, and little water is then added and the crucible is heated at first gently, and then to bright redness, at which it must be maintained as long as vapours are disengaged. A single operation will generally complete the decomposition. The residue is treated with sulphuric acid, and the excess of this acid is driven off evaporation. When the sulphates formed are not completely dissolved by water acidulated with hydrochloric acid, the insoluble residue must be treated with a fresh portion of the fluoride. The temperature should not be raised too high during the operation, for in that case if the silicate contain alumina, a fluoride of aluminium will be formed, difficult to decompose by sulphuric acid.

IV. TECHNICAL CHEMISTRY.

The Bleaching of Paper.—M. Didot[6] has found that by passing a current of carbonic acid gas through the pulp subjected to the action of hypochlorite of lime, the time occupied in the bleaching is reduced one half. M. Didot has invented an ingenious apparatus by means of which he is enabled to make use of the carbonic acid from the chimney freed from the soot and other matters which accompany it.

SCIENTIFIC NOTES AND QUERIES.

Estimation of Mixtures of Acids or Alkalies in Solution.—SIR,—An error should be promptly acknowledged when pointed out. I have just received the CHEMICAL NEWS, No. 13, and feel much obliged to your correspondent who has there pointed out—what I through inadvertence neglected to observe—that in the method which I proposed in No. 9 for estimating mixtures of acids and alkalies, the equations are not really distinct, and consequently the method is worthless.—*E. G.*

LABORATORY MEMORANDA.

New and Easy Mode for Condensing Carbonic Acid on the Small Scale.—Take a piece of glass tubing about 10 inches long and ¼ inch in diameter, close it at one end before the blowpipe; then heat about an inch of it in the middle of its length, so as to bend it easily; and when it is sufficiently heated, with the one hand press upwards and with the other downwards, so as to produce parallel lines with the two ends of the tube at the distance of about half an inch. One part of the tube is by this means raised above the other, whilst the middle

forms as it were a common bent neck to two bottles. This done form to the open end of the tube a good rim which can afterwards be used for fixing a good cork, previously besmeared with putty. When the apparatus is made, introduce by means of a tube syringe into the sealed end half a drachm of pure concentrated sulphuric acid, taking care that the sides of the upper part of the tube are not wetted by the acid; this done, incline the tube so as to keep the acid in the lower end of the tube, and introduce by a fine spatula 2½ scruples of powdered carbonate of ammonia, taking great care not to shake any of it into the acid before the open end has been closed by the cork and secured with copper wire to the rim of the tube. As soon as the tube is thus securely closed, shake the whole of the carbonate of ammonia into the acid and press the tube upon a bladder filled with a freezing mixture, so as almost to bury it in the bladder. The whole may then be covered with a glass bell to prevent the action of the surrounding atmosphere. In placing the tube upon the freezing bladder care must be taken to incline the upper part of the tube so that the condensed carbonic acid can collect in the upper portion of the bent neck. By this manipulation a small quantity of condensed carbonic acid can be prepared in ten minutes, and if the glass tubing chosen for the apparatus be sufficiently strong it may be washed out and used again and again.—*Edward R. H. Unger, Ph.D.*

MISCELLANEOUS.

Coal-oil manufacture in America.—An approximative estimate of the quantity of illuminating coal-oil manufactured daily in the United States, during the month ending December 31, 1859, exhibits the following figures: —

Name or place of works.	*gals.*	*Name or place of works.*	*gals.*
Downer, Boston, Mass.	1,500	K. C. C. M. & O. M. Co.	
Glendon, Boston, Mass.	1,000	Kanawha, Va.	300
East Cambridge, Mass.	800	G. R. C. & O. Co. Kanawha, Va.	300
Page & Co. Mass.	600		
Suffolk, Mass.	300	Greer, Kanawha, Va.	200
Portland, Maine	500	Staunton, Kanawha, Va.	—
New Bedford	300	Atlantic, Kanawha, Va.	—
Hartford, Conn.	200	Maysville Co. Ky.	400
Kerosene, New York	2,500	Union Co. Ky.	600
Columbia, New York	800	Ashland, Ky.	—
Carbon, New York	300	Covington, Ky.	—

Pittsburgh (four firms)	2,000	Phœnix, Cincinnati	200
Great Western, Ohio	500	St. Louis, Mo.	200
Newark Region, Ohio	2,500	Otherwise	3,500
Wheeling, Va.	200		
	Total number of gallons daily		22,750

We will not assert that the estimate is quite correct — some establishments are probably over, others underrated; yet we believe that the sum total is a pretty close approximation to the actual quantity of burning coal-oils now made daily in this country. The produce of the oil-springs has been omitted, as a reliable statement about their produce could not be procured. We will now draw a few general conclusions. It is presumed there have been sold by the several manufacturers of coal-oil lamps and burners from 250,000 to 300,000 dozen burners and lamps, of which about 150,000 dozen are in use, the balance being in the hands of dealers. A coal-oil lamp will consume about 4 gallons of oil during the year. The amount of oil burned by the above 1,800,000 lamps is consequently 7,200,000 gallons per year, or about 20,000 gallons every day. This shows that the amount of oil manufactured is in advance of that consumed.

In order to make 22,750 gallons of burning oil it will require 75,000 gallons of crude coal-oil, to make which requires 60,000 bushels of cannel-coal.

It will cost, to build crude-oil and refining works, to make the named quantity of oil each day, 3,000,000 dollars; but the actual outlay for the oil-works at present at work, does not fall short of 8,000,000 dollars.

The value of chemicals used in the purification of coal-oil will amount to over 2000 dollars per day.

The number of barrels used to hold coal-oil will be between 500 and 600, representing the value of 1000 dollars, and the labour of 400 men.

The value of the burning coal-oil itself will amount to over 16,000 dollars per day, or more than 5,000,000 a year.

All of this does not include heavy oil and paraffin, the sale of which is limited and uncertain.

The number of workmen employed in the several coal-oil works in this country will reach 2000; that of miners engaged in mining cannel 700 or more. Besides this, there are a large force of men employed in making lamps, burners, wicks, chemicals, &c.

If we take into mind that two years ago there were only two or three oil-works in this country, the above statements form a strong illustration of the impetuous energy with which the American mind takes up any branch of industry that promises to pay well. As far as coal-oil is concerned, the rapidity with which the manufacture of this beautiful illuminator has been propagated amounts (like the cultivation of the *morus multicaulis*, some years ago) to a mania.—*Scientific American.*

Charge of Manslaughter against a Druggist.—John Reeve a very respectable young man, surrendered to take his trial for the manslaughter of Thomas Benjamin Cole. The prisoner carried on the business of a chemist at Canterbury, and his brother, a youth of seventeen, acted as his assistant. The deceased was a young man, a tailor, at Canterbury, and on the 19th of December he complained of a sick headache, and went to the prisoner's shop and obtained a draught and some pills. On the following day he sent his sister to the prisoner's shop for some more medicine, and he handed her a phial which was supposed to contain the ordinary black draught, and told her that her brother was to take it with the pills. The deceased took the draught as directed, and very shortly afterwards he became very ill, and a medical gentleman named Andrews was sent for, who from the symptoms he exhibited formed an opinion that he was suffering from epilepsy, and he prescribed some remedies which had no effect, and the deceased died a few hours afterwards. A coroner's inquest was held upon the body, when the jury, upon the evidence before them, returned a verdict of "Natural Death." The result of further inquiries that were made, however, left very little doubt that a quantity of opium had been by mistake administered in the draught taken by the deceased. There was, however, no evidence to show by whose hand the draught was made up, and according to the medical testimony the symptoms exhibited by the deceased were more in conformity with the supposition that the death arose from epilepsy than from a narcotic poison. The learned Judge having summed up, the jury, after a short deliberation, returned a verdict of Not Guilty.

Poisoning by Oil of Vitriol.— A man aged 54 was admitted into the London Hospital on March 3, having swallowed about two ounces of strong oil of vitriol. His tongue and lips were whitened and excoriated, and he suffered excruciating pain referred to region of the stomach. Chalk and milk were freely administered, but he died about six hours after taking the poison. The act was suicidal. This made the seventh case of poisoning by one of the strong mineral acids, admitted into the London Hospital within the last few months.

The Adulteration of Food or Drink Bill. — On Wednesday afternoon the House went into committee on the Adulteration of Food or Drink Bill, commencing at clause 4, which was agreed to, as were also clauses 5 to 10. Mr. KER moved that clause 11, limiting the operation of the bill to England, should be struck out. On a division, the motion was negatived by 101 to 88; majority, 13. So the clause was retained. A division was taken on clause 2, the consideration of which had been postponed, and which was adopted by 123 to 16; majority, 107.

ANSWERS TO CORRESPONDENTS.

*** In publishing letters from our correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

W. M. (Manchester)—We have not yet been able to meet with the information you need. Thanks for the offer.

THE CHEMICAL NEWS.

Vol. I. No. 16. — March 24, 1860.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On a Simple and Expeditious Method of Estimating Phosphoric Acid and its Compounds, by E. W. Davy *M.B. M.R.I.A. Professor of Agriculture, Agricultural Chemistry, to the Royal Dublin Society.*[1]

The want of a simple and expeditious method of estimating phosphoric acid and its compounds, has long been felt, most of the means devised being tedious and complicated. After much investigation, the author has devised a method founded on the fact that phosphoric acid possesses a great attraction for peroxide of iron. When a persalt of iron is added to a solution containing phosphoric acid an insoluble phosphate is produced. This fact has long been known, and different methods founded on it have been devised by Berthier, Kobell, Raewsky and others, for the estimation of phosphoric acid and its compounds. But as each of those methods requires a considerable time for the collecting, washing, drying, igniting, and weighing of the precipitated phosphate of iron, the author proposes to dispense altogether with those operations by simply adding a solution of iron of known strength to the phosphate, and ascertaining the point when enough has been added to combine with all the phosphoric acid present.

The standard iron solution is made by dissolving clean pianoforte wire in pure hydrochloric acid, and sufficient nitric acid is added to convert the proto- into per- chloride of iron. Any free hydrocloric acid is then carefully neutralised with caustic ammonia, which is added until a little peroxide remains undissolved on shaking the mixture. Acetic acid is now added to dissolve the precipitated oxide, and when the solution is effected the mixture is largely diluted with distilled water and graduated in the ordinary way, so that the amount of iron in a given quantity may be known.

This solution may be kept a considerable time without undergoing change, and is therefore preferable to the acetate and other salts of iron which have hitherto been employed.

The next step is to prepare the phosphate. If insoluble (as is generally the case) it is dissolved in an acid. Ammonia is added until the solution is decidedly alkaline, but not in large excess, and then enough acetic acid to completely redissolve the precipitated phosphate, and leave a slight excess. The standard solution of iron is then carefully added from Mohr's alkalimeter, or any other convenient form of volumetric apparatus, till the iron begins to be in slight excess, which is ascertained by taking a drop of the mixture (after it has remained a few minutes with occasional stirring) on a glass rod, and touching with it a piece of thick filtering paper, placed over another piece of paper which has been soaked in a solution of gallic acid and dried. The insoluble phosphate of iron is retained on the filtering paper and the solution which passes down to the lower shows at once by the purple stain when sufficient iron has been added and a minute excess exists in the mixture. If this excess is very minute, the stain will become more visible when the gallic acid paper is dried. The results should be controlled by repeating this experiment a second and third time, having the phosphate dissolved in a given quantity of solution, and taking a certain amount of it for each determination.

The author's experiments have clearly shown him that under the conditions in which the iron and phosphoric acid are placed, a compound having the uniform composition ($Fe_2O_3.PO_5$) is produced, and therefore the objections hitherto made to the volumetric method of estimating phosphoric acid are obviated. Experiments made with pyrophosphate of magnesia, tribasic phosphate of lime, and anhydrous pyrophosphate of soda, all gave results agreeing closely with the calculated composition, as will be seen by the following table:

Amount of iron required to combine with the PO_5 contained in one grain of

	By calculation, parts of a grain,		By experiment.
Pyrophosphate of Magnesia	0·5000	1st experiment	0·5000.
	,,	2nd ,,	,,
	,,	3rd ,,	,,
	,,	4th ,,	,,
Tribasic phosphate of lime	0·3589	1st experiment	0·3600.
	,,	2nd ,,	,,
	,,	3rd ,,	,,
	,,	4th ,,	,,
Anhydrous pyrophosphate of soda	0·4179	1st experiment	0·4200.
	,,	2nd ,,	,,
	,,	3rd ,,	,,
	,,	4th ,,	,,

In all cases, however, bibasic salts must be converted into tribasic before the addition of the iron solution, which may be done by heating them with a little hydrochloric acid; and then the solution must be allowed to cool before the estimation is made, as heat alters the conditions and gives rise to a different compound of iron and phosphoric acid.

The method appears particularly useful for estimating the quantity of soluble and insoluble phosphates in superphosphate of lime as well as other manures, in the ashes of plants, and in all cases in which an expeditious determination of the phosphates is required.

Solubility of Mercury Precipitates in Alkaline Salts, by J. Attfield, *Demonstrator of Chemistry at St. Bartholomew's Hospital.*

The precipitates that are obtained on adding an alkali to the solution of a mercuric or a mercurous salt, are described in the ordinary text-books as being insoluble in an excess of the reagent. Practically, however, this is far from being the fact; the acid with which the mercury was combined forming an alkaline salt in which in nearly all cases the mercury precipitate is more or less

[1] Abridged from the *L. E. and D. Phil. Mag.*

soluble. Solution of the precipitate of course takes place more readily if the mercury solution contains free acid, or if another salt be present, the base of which is soluble in free alkali; a larger quantity of alkaline salt being in either case formed.

If, for example, to a tolerably strong solution of mercuric nitrate there be added a little nitric acid, or such a salt as nitrate of copper, and then solution of ammonia, no precipitate is obtained, or one which rapidly dissolves on adding excess of the ammonia. Indeed if the precipitate first formed be collected and washed, and then simply digested in solution of ammonia, it will be found to be soluble; a result one would scarcely have expected after reading the following in Gmelin's *Chemistry* (*Cav. Soc. Trans.*) vol. vi. p. 14: "Caustic ammonia and carbonate of ammonia form white precipitates with mercuric salts. This precipitate usually contains a compound of amide of mercury with undecomposed mercuric salt, and is insoluble in excess of ammonia." At p. 94, however, of the same volume, is found an apparent explanation of the matter. It seems that under the circumstances — circumstances that in class-teaching are not uncommon — a compound is formed containing one equivalent of mercuric amide with five equivalents of mercuric nitrate, and that this particular compound *is* soluble in excess of ammonia.

Briefly; it will be found on experiment that these mercuric-amido precipitates are all more or less soluble in solutions containing much nitrate, sulphate, chloride, or some other salts of ammonium. Mercuric arseniate and phosphate are similarly affected.

Salts of the fixed alkalies interfere with the formation of mercuric precipitates; but to a very much smaller extent than ammoniacal salts. A trace of mercuric oxide dissolves in large excess of strong caustic potash or soda, but a notable quantity dissolves in strong solutions of the salts of those bases. Mercuric iodide is sparingly soluble in water; the solubility is however considerably increased by the presence of alkaline salts.

Mercurous precipitates are all as soluble in ammoniacal salts as mercuric precipitates; and moreover are as soluble in the salts of the fixed alkalies as they are in those of ammonia. In most of these cases a decomposition of the mercurous compound occurs, mercuric salt being dissolved and metallic mercury left insoluble. Ordinary commercial calomel when agitated with a saturated solution of chloride of ammonium is largely dissolved, a small quantity only of metallic mercury remaining insoluble. Wittstein is quoted (*op. cit.* p. 56) as having found that "calomel is soluble for the most part in sulphate of ammonia, but very sparingly in the nitrate and succinate."

Mr. Spiller (*Qu. Journ. Chem. Soc.* vol. vi. p. 115) has remarked that alkaline citrates interfere with the precipitation of mercury.

No doubt the salts of the alkaline earths retard the formation of mercury precipitates. At p. 12 of the volume of Gmelin's *Handbook*, already referred to, it is stated that "chloride of magnesium and chloride of calcium when boiled in the state of concentrated solution with mercuric oxide give up to it a portion of their acid." In the *Pharm. Jour.* also (2nd series, vol. i. p. 194) Mr. Rogers notices that when calomel is agitated with lime water, mercury is taken up by the liquid.

In conclusion, it may be remarked that the above sources of loss in the preparation, detection or estimation of mercury compounds may be avoided to a considerable extent by using dilute solutions and by allowing the mixtures to stand for some time.

TECHNICAL CHEMISTRY.

Arsenical Paperhangings.

Much has already been written on this subject, nevertheless, it may be acceptable to some of your readers, to possess a short summary, by one practically acquainted with the various different kinds of papers of that description.

The arsenical green or arsenite of copper is a highly poisonous compound of arsenious acid and oxide of copper, with sometimes a portion of acetate of copper, and is commercially known as Scheele's or Schweinfurth green. It is an insoluble precipitate obtained by boiling solutions of arsenious acid or arsenites of potash or soda, with sulphate or acetate of copper. The washed precipitate is dried at a temperature of 212°F., a temperature unable to decompose or volatilise any of the arsenious acid of the compound. This dry insoluble precipitate is levigated with a glutinous vehicle such as gum, dextrine, &c. to render it applicable for printing; additions of chalk or other coloured media give the different shades of green. These colours when painted or printed on paper constitute the green arsenical papers in question, which for convenience sake we may divide into two classes, unsized and sized; as however flock-papers have become of considerable importance, it will be necessary to say a few words about their manufacture as well. Flock papers are covered with a thick uniform layer of variously coloured woollen fibres, which constitute the flock, and owe, like similar woollen materials, their colour to a process of dyeing, for which purpose a soluble colour and no insoluble precipitate is necessary. The green of the flock is perfectly harmless and free from arsenic; its manufacture is almost solely carried on in France, where, in all probability, an indigenous vegetable dye (*grains d'avignon* or French berries) enables the manufacturer to maintain this monopoly in preference to other countries.

Papers which contain this green flock over the whole surface may therefore be considered free from arsenical compounds. When this, however, this is only partly done and the paper intermixed with other colours and drawings, these latter have to be separately examined and placed in either of the two before-mentioned classes.

By *unsized* papers we mean such whose colours after being printed are simply allowed to dry without undergoing any further process or treatment; *sized* papers however, have in addition to this an extra coat of size or varnish over their colours, which protect them from easily rubbing off.

Since the theory of the spontaneous evaporation or volatilisation of the arsenic in the paint gave way to the more palpable mechanical agency of servants' brooms and dusters, we required neither aspirators nor microscopes to seek for its presence; arsenical dust can be collected by the ounce, and sheets of copper gauze and foil well covered with it. With the loss of this theory, the arsenic question assumes a more tangible and practical character, and enables us to find remedies or protection against their evil consequences. It is

evident that paints of a powdery and friable character, when thick and loosely laid on paper, will soon, by touch or rougher treatment, become detached and be mixed with the atmosphere, and should such an unsized paper still contain any flock, especially on a green coloured ground, the danger will naturally be increased. The simple arsenite of copper is a comparatively heavy substance, which when once loosened would soon fall to the ground, and subsequently be removed; the light floculent woollen material however will float in the air for some time, and when mixed with particles of arsenical paint will bring this dangerous body in continual contact with those whose more refined senses are keenly perceptive of its pernicious effect. But besides this really dangerous property, these flock papers are of a thick, spongy consistence, and require when fastened to the walls a considerable amount of paste and moisture, which for some time afterwards will give a room a disagreeable moist atmosphere, very liable to cause headache, a circumstance which naturally has led to the suspicion that the danger lay principally in the flock and not in the more hidden, but nevertheless, solely dangerous ingredient.

It would be therefore unwise to advocate an indiscriminate use of these green papers, but it is equally uncalled for to look at every green colour on our walls with fear or suspicion. Many may have suffered from living in rooms decorated with incomplete and inferior arsenical papers, but it is equally certain that still more have and still enjoy the best of health in rooms decorated with green papers of a better and more careful manufacture. A green arsenical colour well prepared with a sufficient amount of gummy matter, and not too thickly laid on the paper, and well sized over, so that a reasonable amount of friction with cloth or hand is unable to remove any colour, is a perfectly harmless ornament, which may be selected without fear. Should it contain any flock, it would be satisfactory to know that this flock is not fixed on a green arsenical ground, as an elevated rough surface is more liable to be detached than the plain smooth ground, and when loosened it would in all probability carry some of the green colour underneath with it. Lastly, in examining green papers for arsenic, we know with what diffidence hydrochloric acid and metallic copper tests must be confided, and how suspicious the bright yellow precipitate looks which HS produces in our acid liquor; neither is the presence of copper alone a sufficiently satisfactory evidence for arsenic in any green pigment. A more simple and safer mode of testing these papers consists in scraping a few grains of the suspected green colour off, introducing it into a dry test tube by means of a slip of paper, so as to keep the sides of the test glass clear. By closing its aperture and gently heating it in the gas flame the green powder soon becomes carbonised, and if arsenic is present this sublimes as arsenious acid perfectly distinct and visible above the residue. When cold the carbonised residue is removed, the test tube filled to about a quarter with distilled water, a drop or two of liquor potassæ added, and the mixture boiled. This solution is respectively tested with ammonio-nitrate of silver, or ammonio-sulphate of copper, when the characteristic yellow and green precipitates will further point to the nature of the directly obtained arsenical sublimate. It is evident that in the above process the arsenic can only be derived from the green colour of the paper, whose shade and amount of green will in most cases give us a sufficient estimate of the arsenic they contain.—*J. S.*

PHARMACY, TOXICOLOGY, &c.

Purification of Castor Oil.

It is well known that castor oil on being kept a long time undergoes some changes. It gets thick and becomes rancid, at the same time acquiring an acid taste, which remains in the throat some time after the oil has been swallowed. M. Parvesi, of Turin, has found an easy means of purifying this rancid oil. He mixes 1000 parts of the oil with 25 of animal charcoal, and 10 of calcined magnesia, and leaves them together for three days at a temperature of 68° to 78° F., often stirring or shaking the mixture. The oil is then filtered off, and is found to be limpid, colourless, odourless, without taste, and easily soluble in alcohol. It congeals too at a lower temperature than before, and is in that respect superior to the ordinary oil.

Preparation of Mercurial Ointment.

M. Delarue[1] in an article on *The Influence of North Wind on the Preparation of Mercurial Ointment*, says that a long experience has convinced him that the presence of water in the lard greatly interferes with the extinction of the mercury. He therefore specially prepares the lard by heating it over a quick fire to 125° or 130° C. to expel all the water. He then sets it aside for three days. When the ointment is prepared he first mixes the whole of the mercury with a third of the lard, and then gradually adds the remainder. Trituration for two hours will suffice to obtain an ointment presenting all the characters required.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY, 15 March 1860.

Dr. Miller, *V.P. in the Chair.*

Mr. Hadow read a paper *On the Composition of the Platinid-cyanides*. He first adverted to the platino-cyanides, which are extremely stable salts having the general formula $MCy.PtCy$ or $MPtCy_2$. These salts are remarkable for the great beauty and variety of colours their crystals exhibit, while their solutions are colourless and transparent. Thus the platino-cyanide of magnesium is deposited from a colourless solution in large prisms of a deep red by transmitted light, but of a brilliant iridescent green and purple by reflected light. In endeavouring to prepare this salt by the method of Quadrat, namely, by evaporating together solutions of sulphate of magnesia and platino-cyanide of potassium and extracting with mixed alcohol and ether, the author by using alcohol alone, obtained in addition to the ordinary deep red salt one of a paler colour, and of a modified iridescence, which proved to be a double platino-cyanide of magnesium and potassium, $MgPtCy_2 + KPtCy_2 + 2HO + 5aq$. The platino-cyanides may be converted into the salts known as platinid-cyanides by the action of chlorine, bromine, nitric acid, &c. They are usually represented by the formula $M_2Pt_2Cy_5$, and are considered to result from the addition of 1 atom of cyanogen to 2 atoms of the platino-cyanide. These salts act like the ferrid-cyanides by exerting a powerful bleaching agency in presence of free alkali, and by liberating iodine from iodide of potassium. The acceptance of the above formula, however, renders it extremely difficult to account for the

[1] *Le Moniteur Scientifique*, 1 Mars 1860.

formation of the salts by the action of chlorine, &c. or to account for their reduction from alkaline solutions to the state of platino-cyanides without the production of cyanide of potassium. Mr. Hadow's analysis of the platinid-cyanides showed, in the first place, that the proportions of cyanogen, platinum, and basylous metal, were the same as in the platino-cyanides; and in the second place, that the platinid-cyanides contained chlorine, bromine, or peroxide of nitrogen, according to the reagent used in producing them. The determination of the chlorine directly was unsatisfactory, but the author effected the estimation very readily by ascertaining with a standard solution of permanganate of potash what quantity of chlorine was required to convert the platinid-cyanide into the ultimate product of the action of chlorine upon the platino-cyanide, namely, the perchloro-platino-cyanide $KPtCy_2Cl$. In this way the so-called platinid-cyanide was found to have the composition $6(KPtCy_3)Cl$. This salt, when acted upon with a solution of zinc, broke up into a platino-cyanide, which was precipitated, and a perchloro-platino-cyanide which remained in solution. Conversely, by adding 1 proportion of perchloro-platino-cyanide to 5 proportions of platino-cyanide, the so-called platinid-cyanide, or, as the author termed it, the chloro-platino-cyanide was deposited in crystals; so that it appears to be really a double salt $5\,KPtCy_3 + KPtCy_2Cl$. The compounds produced by the action of bromine and nitric acid upon the platino-cyanide were believed to have a similar constitution. No iodine compound has been produced. Analogous compounds, however, containing the radical SO_4 in the place of chlorine, were formed by adding peroxide of lead to solutions of the platino-cyanides, acidulated with sulphuric acid.

Mr. Morreland read a paper *On a new Ammonio-chrome Compound*. The salt was prepared by adding finely powdered bichromate of potash to fused sulphocyanide of ammonium. A brisk reaction soon took place, and the residue having been washed with water was dissolved in alcohol, from which the new compound crystallised out in forms of the regular system. The composition of the salt was represented by the formula $Cr_2Csy_3.2NH_4O$. Heated in a closed tube it gave off sulphide of ammonium with other products, and left a residue of sulphide of chromium.

Mr. Hooker read a paper *On the Analysis of a Water from the Superficial Strata of the London Basin*. The water yielded 183·7 grains of residue in a gallon. It was remarkable for the large amount of nitric acid it contained, namely, 33·2 grains in a gallon. The nitric acid was estimated by Nesbit's process, that is to say it was reduced to the state of ammonia by means of nascent hydrogen generated from zinc and sulphuric acid, and the ammonia thus produced evolved and neutralised by a test acid.

The anniversary meeting for the election of officers, report of council, &c. will take place on Friday, March 30, at 8 P.M.

SOUTH KENSINGTON MUSEUM, 14 *March* 1860.

On the Flavour of Food, by Ed. Lankester, *M.D., F.R.S.*

CONDIMENTS AND SPICES.

A passage occurs in the life of a practical philosopher which is well known to a large number of readers in England, and which so well illustrates the subject of the evening that I will read it.

"'Weal pie,' said Mr. Weller, soliloquising, as he arranged the eatables on the grass; 'Wery good thing is a weal pie, when you know the lady as made it, and is quite sure it an't kittens; and arter all though where's the odds, when they're so like weal that the wery piemen themselves don't know the difference?'

"'Don't they, Sam?' said Mr. Pickwick.

"'Not they, sir,' replied Mr. Weller, touching his hat. 'I lodged in the same house with a pieman once, sir, and a wery nice man he was — reg'lar clever chap too — make pies out o'anything, he could. 'What a number o' cats you keep, Mr. Brooks,' says I, when I'd got intimate with him. 'Ah,' says he, 'I do — a good many,' says he. 'You must be wery fond o' cats,' says I. 'Other people is,' says he, a winkin' at me; 'they an't in season till the winter though,' says he. 'Not in season!' says I. 'No,' says he; 'fruits is in, cats is out.' 'Why what do you mean?' says I. 'Mean!' says he; 'that I'll never be a party to the combination o' the butchers to keep up the prices o' meat,' says he. 'Mr. Weller, says he, squeezing my hand wery hard, and vispering in my ear; 'don't mention this here agin, but *its the seasonin' as does it*. They're all made o' them noble animals,' says he, a pointin' to a wery nice little tabby kitten; 'and I seasons 'em for beefsteak, weal, or kidney, 'cordin' to the demand; and more than that,' says he, 'I can make a weal a beefsteak, or a beefsteak a kidney, or any on 'em a mutton at a minute's notice, just as the market changes and appetites wary!'"

Well that is the text of my lecture to night, "*it's the seasonin' as does it*," and you know that condiments and spices are the seasoning with which we make our food pleasant; and, after all, if you consider what makes the difference between the various kinds of food, you will find that Mr. Brooks's philosophy is the correct one. It is the taste and flavour that make the different varieties of food. Now the nervous system is as much formed for the appreciation of these tastes and flavours, as the ear is for sound, and there is as much relation between sounds as addressed to the ear, and colour as addressed to the eye, as there is between different flavours as addressed to the palate. The man who appreciates sound and colour best, is also the most capable of appreciating the taste and flavour of a meal; and we shall find that as intense colours overcome faint colours, as intense sounds overcome sounds which are not so loud, so intense tastes and flavours overcome other tastes and flavours; and just as we would for a concert arrange the music with regard to the variation and selection of the different sounds, so we should for a meal arrange the variation and selection of our tastes and flavours. The same Creator who created the ear or the eye, created the taste, in order that we might appreciate the charming things around us.

Now I must in the first place draw attention to the tongue. The tongue alone, however, is not concerned in this appreciation of tastes and flavour, for we find that the nose is jointly occupied with it; for there are certain flavours that we should hardly taste at all had we no noses, and there are certain of our foods which altogether address themselves to the sense of smell. Take cinnamon, nutmegs, or cloves, for instance; if we put some of these into our mouth and close the nose, we can hardly appreciate the flavour; so it is evident that we frequently use the sense of smell in the exercise of the organ of taste. It is a curious fact that those nerves which give the sense of taste or flavour are the nerves of common sensibility, that is to say, those by which we feel the *touch* of any object upon the external surface of our bodies by friction or otherwise. When considering the fact which I have just mentioned, that some things are not really tasted at all unless they are smelled, some persons have supposed that there is no real function of taste, but that what we say we taste, we either smell or feel, or that the sensation of taste is compounded of both. The better way to test that is to apply something to a different part of the body, such as quinine or sugar to the leg, and you will find that they produce no impression of taste or flavour in the leg; although if you put quinine upon the tongue, you will have an excessively bitter taste, and with the sugar—sugar of lead and other substances—a sweet taste, and a taste of salt with salt, sulphate of soda and a number of other things; so that we can thus prove that there are certain things which we really taste. Now we will call these substances which are tasted *sapours*, in opposition to those which are called odours.

Passing on from the nerve of taste I would just say with regard to the nose that it is the organ of smell, and that it has a distinct nerve of smell. Now there are certain things which address the organ of smell which are not taken up into the mouth. Thus we have a variety of gases and things which we call scents, odours, perfumes, smells and

stinks, which address themselves to these nerves. We find that this function is developed greatly in the lower animals, and even among the wild races of men this function of smells is very much greater than among cultivated and civilised races; and the fact of man having a sense to guide him in taste and smell is of importance where our intelligence and sense tells us what is good for us, as sometimes happens in the case of persons in illness judging as to what is good for them better than the doctor; doctors have sometimes yielded to a patient's wish for some particular food in consequence of this instinctive desire, and the patient has been very much better for it. As instances of the use by the lower animals especially of the sense of smell, I may say that they will instinctively reject food which is poisonous, however carefully you may wrap it up, even when pressed by much hunger. Monkeys, cats, dogs, and animals of the higher class will pertinaciously reject it, their determination arising from the sense of smell. It is not only from the olfactory nerve that provision is made to guard against the destruction of the animal; a man may be sometimes placed under circumstances in which he will be exposed to carbonic acid, chlorine, or a variety of gases which if taken into the system would destroy him; he has then, besides the sense of smell to detect these gases, the fifth nerves which produce the sensation which we call sneezing, which are titillated by various powders and gases which would act injuriously if they went into the lungs. This act of sneezing is the act of throwing away or getting rid of that which if a man got into his lungs would injure him. When a man sneezes he draws back, in cases where if he went forwards he would soon repent, and perhaps cause very serious consequences. The taste has reference to food, the smell has reference to that which probably may be good for food, while the nerves distributed with the olfactory nerves have reference to the gases.

I now pass on to consider, in the second place, the nature of the various kinds of sapours and odours which we find in our food. To a thoughtful mind, there are many ways of classifying these, but I may speak of them as agreeable and disagreeable odours and flavours, addressing both the organs of taste and smell. In the first place, we have a number of agreeable odours, and these odours may or may not accompany our various kinds of food. I will just allude to some of these. I have here a number of those which are occasionally used to put into food, and occasionally to put into perfumes: these are agreeable odours. Then, again, we have another set, which are disagreeable, arising from the mineral, the vegetable, or the animal world. Substances of the vegetable and animal worlds in decomposing produce sulphuretted hydrogen, which is a disagreeably offensive odour, and injurious to health. I will glance at the fact that the carburetted hydrogen in the gas which we burn gives out a disagreeable odour. Sometimes these disgusting odours, by custom and habit, become agreeable, and sometimes, in the same way, disgusting food, by custom and habit, becomes agreeable food: high game and things of that sort are not generally rejected, because we are accustomed to the flavour. There is a story told of a king of Prussia being confined in a prison a long way from the sea-shore, where they never could get oysters until they were what is called a little gone; he being fond of oysters became accustomed to these, and afterwards never could endure the presence of fresh oysters. This will illustrate a curious fact which we shall meet with, that some odours, naturally disagreeable, become agreeable by habit. You will find it very difficult to make children take things which, when they grow up, they acquire a taste for — olives, for instance, or tobacco. It is to those tastes and flavours which are most commonly employed in food to which I would draw attention more particularly, and I will say that those tastes and flavours are all more or less composed of the same elements.

When speaking of food on a former occasion, I said that the four constituents composing our food were carbon, hydrogen, nitrogen, and oxygen. These are the very elements which arranged and rearranged in a variety of ways form the flavours which after all distinguish one food from another. Of these various tastes and flavours there are a series which we call by the name of essential oils, and another which we may refer to as a class of bodies called ethers; but before speaking of essential oils or ethers particularly, I will call attention to the production of common ether. I have here some which you will recognise as having that smell which is so refreshing to persons who have a difficulty in breathing; you will soon smell it in the room if I take the cork out. Now that ether is made from alcohol. Alcohol is the result of decomposition of sugar. If we take grape sugar we find it composed of 12 parts of oxygen, 12 of hydrogen, and 12 of carbon; and alcohol, which is the substance at the foundation of all our odours, is composed of 4 of carbon, 6 hydrogen, and 2 oxygen, arranged as 4 of carbon, 5 hydrogen, 1 of oxygen, and 1 atom of water. Now if we take away from it the water we have ether left, which is an oxide of the substance ethyl, composed of 4 carbon and 5 hydrogen, the same elements that are in coal gas. The whole of these scents and odours arise from componds of carbon and hydrogen. This substance ether, which is an oxide of ethyl, will combine with acids, so that we have sulphates of the oxide of ethyl, tartrates and citrates of the oxide of ethyl, &c. A distinguished French chemist has discovered that one compound of oxygen and hydrogen and carbon, combining with chlorine, with iodine, and with nitrogen, has been capable of producing 1020 different compounds; and there are thousands and tens of thousands, nay hundreds of thousands, of compounds which may be similarly produced, and which give flavours and odours, and scents and peculiarities, in thousands of directions which we know of, and in hundreds and thousands of directions which we know nothing of, and this is the direction in which organic chemistry is going in the present day. What then is their action on the system? I will take any of these upon this table: there is orange flower, that contains one of these compounds, then the melon, that contains another of these ethers, and I might take nutmeg, quince, pear, or apple, or any other fruit, and I should find that they all contained essential oils, which are volatile bodies — compounds of carbon and hydrogen — arising from these substances and giving their taste and flavour to the tongue or nose. It is one of the most curious features in the history of modern chemistry that not only has the chemist been able to show the nature of these compounds by pulling them apart, but he has begun to find out the way to put them together again; and the chemist can now produce in his laboratory what is ordinarily produced by nature in the laboratory of the plant or fruit. One of the first things that was formed in this way was the oil of bitter almonds. You know that bitter almonds contain an oil which may be extracted from them, and has a very pleasant flavour or scent. It is used in custards, puddings, cakes, and in a variety of other ways; and this essence obtained from peach kernels, and these other scents, are also used for various similar purposes. There are two or three substances ordinarily sold in the present day for oil of bitter almonds which are manufactured from other matters. I have here a substance called benzol, which is a compound of carbon 10 and hydrogen 6, instead of 4 and 5. Now this benzol can be formed from other substances just in the same way as the chemist can form the ether, by decomposing certain compounds and leaving the carbon and hydrogen in the above proportion; and this is sold under the name of benzol, benzine, and benzoline, and is probably known by some persons present on account of its being used for cleaning gloves, it having a greater solvent power in relation to dirt than ether or alcohol.

This benzol is obtained from coal tar which is a most valuable substance, and although it is rejected at the gas factories, it is likely to become of most essential service to man in the manufacture of very many things. By adding nitric acid to benzol we obtain this nitro-benzol, or artificial oil of bitter almonds. There is another substance, hippuric

acid, extracted from the drainage of our stables which, when submitted to the action of heat, can be made into nitro-benzol, so that, as I have said in a former lecture, there is no such thing as real dirt, for dirt is merely matter not in its proper place; although used by man in a thousand ways, the elements are still pure, and only have to be again reunited. Hippuric acid is obtained from the stables, and its product is introduced into the most delicate soap and applied to our faces. And this is only one of a series of oils. There is a substance for which we in England have long been celebrated — pear oil — in the manufacture of which no pears are used. We take amyl, which is got from potatoes; it is composed of $C_{10}H_{11}$, and when united with common vinegar or acetic acid, we get a substance which cannot be distinguished from the smell of the jargonelle pear. Here is some of this scent which is sold in the shops, and for the manufacture of which we have been celebrated for upwards of six years. It is out of this manufactured pear oil that this jar of cheap lozenges is made, which are sold in the shops at a penny an ounce. The yellow drops are made of another oil — pine-apple oil — introduced into a variety of forms of confectionary — and here we have our old friend ether coming in again. You have all smelt rancid butter which has been long kept; distil that rancid butter and you will obtain butyric acid, mix that with this ether, and it becomes a pine-apple flavour. Now nature has done the same thing; there has been a manufacture of butyric acid and ethyl going on within that beautiful fruit which we call pine-apple, and here you will taste the essential principles which give the taste to the pine-apples. Then here is the oil of apples. There is an acid in the substance known by the name of valerian, which has an exceedingly unpleasant smell. There are things which for a moment are exceedingly pleasant, but by taking too much they become exceedingly unpleasant. Valerian is of that kind, containing valerianic acid, and that combined with the oxide of amyl constitutes what we know by the name of apple oil, which is used in the apple confectionary. The pleasant taste of apple is produced in that way. Now this oxide of amyl can be got from potatoes, coal tar, and other substances, so that there is no difficulty in making these oils, and so many of them have been made that we shall soon have no difficulty in procuring them, without having recourse to the vegetable kingdom. That these things are composed of carbon and hydrogen I can show you in a variety of ways. By their inflammability, for instance. I have here a little instrument called a spirit-lamp. Here I have some lavender water which you see is burning away very rapidly, and I have here some papers which have been dipped into some of these oils, which speedily disseminate their odours when ignited. You will smell them about the room in a few minutes.

I must now leave this subject and say a word with regard to the action of these oils on the system. When taken into the stomach they act upon the nervous system as well as in the regions of taste or smell, and produce an effect upon the stomach, causing the secretion of a large quantity of gastric acid, and causing digestion to go on better. We instinctively add to meat stews Cayenne pepper and things of that kind, which act as stimulants to the stomach — they act as alcohol and stimulate the nervous system. Persons can get tipsy upon oil of cinnamon and oil of cloves just as they can upon hydrated oxide of ethyl. I have here a wonderful display of *liqueurs* sent down by Messrs. Fortnum and Mason of Piccadilly, liqueurs of France, of Germany, of Sweden, and Norway, and here is one of those which has become celebrated on account of its killing so many Frenchmen lately. It is called absinthe, and is prepared from wormwood. This wormwood, which I now hold in my hand, contains a volatile oil which acts not only as a stimulant to the stomach, but also has a narcotic effect upon the nervous system; and a distinguished French chemist has just discovered that this wormwood contains seventeen deadly principles, any one of which would kill an individual who would venture to ake it. Absinthe contains as much as 20 per cent. of alcohol, and if a Frenchman drank as much absinthe as he did brandy he would soon kill himself. Then, passing on from this substance, I would just speak of the classification of these sapours and odours. I have found considerable difficulty in this, arising from the various terms that are given to them; but I have arranged them under the heads of condiments, spices, fruit flavours, and bouquets, and to these I would now draw attention.

Now what is a condiment? Well I have not been able to get a satisfactory answer, but I have thought that these volatile oils, or ethers, or whatever you may call them, which can be taken with salt are condiments, and those on the other hand that can be eaten with sugar are spices. I have put among the *condiments* as being flavours agreeable with salt — garlic, leek, onions, mustard, pepper, Cayenne pepper, capers, pickles, parsley, celery, coriander, thyme, sage, mint, fennel, mushrooms, morels, truffles. Now looking at these condiments you will find that they all of them contain different kinds of essences, oils or ethers, or whatever you like to call them, and some of them so distinct as to admit of classification. Thus garlick, leek, onions, and assafœtida are condiments. Persons fond of onions will get from onions to leek, from leek to garlic, and from garlic to assafœtida, and so it is in the City, if you go to a chop-house, and ask for your steak to have a little higher flavour, they take the plate, rub a little assafœtida on it and put it before you: you do not know what it is, but find it agreeable. Now how is this? If we take a substance from the region of our pleasant scents and odours, and add to these bases — these hydrocarbons — instead of oxygen, a little sulphur, then you will get things with sulphur smells, — onions, leeks, water-cresses, cabbage. When cabbage is boiled there is the sulphur smell which ascends to the drawing-room, and it is: "Pray shut the kitchen door: you are boiling cabbages." Now in the case of garlic, leeks, and assafœtida, we have a substance called allyl, but in the case of mustard and water-cresses, and those things, we have another substance in addition to the sulphur, carbon, and nitrogen, and that is cyanogen, which when it is united with hydrogen forms hydrocyanic acid, one drop of which kills a man. You see what a fearful thing chemistry is. These substances are all connected one with another, up and down a ladder as it were, in their combinations, but are yet distinct.

Now I come to the peppers, and here our chemistry a little fails us. Peppers are not always the same thing; there is long pepper belonging to one family, and Cayenne to another family, and other peppers belonging to other families; so that pepper is not a term that we can use botanically or chemically.

Here I am reminded of a series of very pretty little bottles which contain condiments and spices, which have been prepared in such a way that about a tenth part is equivalent to the whole substance in its natural condition. They are prepared in France, and as far as I have considered them they are likely to be useful to those persons who desire to study the flavours of taste or smell as they would the sounds of music. I will therefore recommend these soluble spices to the epicure and to those who have the wish to study these things. Now there are two or three other things which have to do with the preparation of condiments, but I must not now dwell upon them. For instance, we may take onions, which contain as an essential oil sulphide of allyl, and let them soak in vinegar, — here I have some chalot vinegar prepared in this way with pure fermented vinegar — this is another way of adding these condiments to our food, and there can be no doubt that vinegar has certain effects on our food by dissolving some things which water and acids would not dissolve. Vinegar, however, like alcohol, may be constantly abused. It acts upon the coats of the stomach so as to prevent their proper healthy action, and instances have been known of young ladies who, wishing to grow thin, have drunk such large quantities of vinegar that they have brought themselves into consumption. Here, again, are other substances which yield a pecular flavour. I mean these mushrooms, which start up in every direction after a

shower in the spring and autumn, and which are so valuable not as articles for diet but for flavour, and which flavour depends upon fungic acid. All these fungi can be made available for condiments. In Russia, and many parts of France and Italy, large quantities of them are consumed, and it is a curious fact, showing how little we know of the nature of these bodies, that the very ones that we think can alone be eaten with impunity cannot be purchased in the Roman markets, the inspector stopping that sort. Morels and truffles are also condiments. The mushrooms may be kept dried and powdered for any length of time, and added as pungents to articles of food.

But I must now pass on to the spices or flavours mostly used with sugar, such as ginger, allspice, cloves, nutmegs and mace, cinnamon, carraways, bay, angelica; and will just say that cinnamon may be taken as the type. It is indebted for its flavour to oil of cinnamon, which may be dissolved out by means of alcohol, and constitutes essence of cinnamon. Oil of cinnamon is also found in the plants *lauraceæ*, which not only yields cinnamon but cassia, which is employed to adulterate cinnamon itself, or is a fraudulent substitute for the essence. Camphor is yielded by a plant called *laureas camphora*. Cloves belong to an order to which our common myrtle belongs, *cefreons rusticus*. Pimento is the unripened fruit of the *metus pimento*, and the oils resemble those which we got from the other order, lauraceæ. Then we have nutmeg oil. In the covering of the nutmeg we have a substance which is called mace, which contains a slightly different oil from the oil of nutmeg itself. Then there are several others which may be classed as spices, all of them containing volatile oils.

Now I have distinguished a certain number of the things which come under the name of fruit flavours, or flavours found in the fruits of plants, not usually called condiments or spices, such as bitter almonds, vanilla, pear, pine apple, raspberry, strawberry, melon, orange and lemon peel, citric, tartaric, malic, and oxalic acids; many of these have been imitated artificially. Thus we find the apple flavour, the pear, and the pine-apple, have all been imitated successfully; but there are others which have not; for instance, the oils contained in the orange peel or the lemon peel. If you look at the outside of the peel of an orange or a lemon you will find a number of vesicles containing the essential oil, and when this is mixed with spirit it is called essence of lemon, essence of orange, and so on. These things which are candied are not eaten because of the peel but of the flavour contained in it. Here I have the angelica, which no one would think of eating alone; but when it is candied the consequence is that the angelica flavour is given to the sugar. Here I have the melon candied, and the cashew flavour given to the sugar. Here is some citric acid which is found in the whole of the fruits belonging to the orange tribe. This citric acid can be extracted in a crystalline form from lemons and oranges. And here is tartaric acid obtained from the grape, which has a very different property from the citric acid. When I put some liquor potassæ into the tartaric acid I obtain a salt called cream of tartar. When wine is made from grape we get a precipitate of tartar; but when it is made from oranges and lemons we obtain no precipitate, it remains in the wine. Here also is another acid, oxalic acid, used for cleaning boot tops and things of that sort, and every now and then it is taken by mistake for epsom salts. It is contained in wood sorel and rhubarb, and this rhubarb is eaten on account of the oxalic acid which it contains; and that is the reason why we eat rhubarb tart whilst we are waiting for the gooseberries and currants. These then are the fruit flavours. There are two or three other flavours which I should like to have mentioned: I am reminded of the vanilla flavour obtained from fruits, which would scent the whole room, and which is put into chocolate and a variety of articles of diet on account of its delicious flavour.

I have put down in the prospectus as a subject for this evening, the bouquets of wines, spirits, and liqueurs. You know what the value of wine is. Here is some old tokay, some wine of Cyprus, some old sack; and here are wines of unmeasured price. And why? If you look upstairs you will see their analyses. They contain water and sugar and acid, as all other wines do; why then do they obtain such prices? It is the *seasoning that is in them — the œnanthic ether*, which is capable of being split up into many varieties of compounds; and then there are obtained those fine flavours which can now only come out of old crusted ports, or which can only be got out of the burgundies or clarets; and there are flavours that can only come out of one hill on the Rhine—the Johannisberg.

If we take nutmeg or any of these spices and distil them with spirit, we obtain liqueurs. Some of those liqueurs are mixed with flakes of silver, in order to imitate a silver beverage, for common people, I suppose; and here they are mixed with flakes of gold for another class of people. I might speak of the flavour of gin with our common juniper berries; I might speak of brandy flavours obtained from common pitch or benzol; I might speak of whisky with an artificial flavour, and rum containing this butyric ether, and it would all tend to show you that that great philosopher Mr. Brooks was right when he said "*Its the seasonin' as does it.*"

SOCIETY OF ARTS, 14 *March* 1860.

SIR T. PHILLIPS, *F.G.S.* (*Chairman of Council*), *in the Chair.*

A PAPER, upon *The Art-treatment of Granitic Surfaces*, was read at this meeting of the society by Mr. JOHN BELL, from which, although perhaps somewhat out of the province of this journal, we will cull a few paragraphs. The lecturer commenced by pointing out the chief characteristics of granite, and the style of art most suited to that material, the enduring nature of which has enabled our *savans* to decipher so much of the history of Ancient Egypt and Assyria. The art models of the Egyptians were generally taken from the vegetable world, the "Sacred Nile" supplying him with plants and flowers in abundance, his principal types, however, being the *papyrus* and *lotus*. *Incised relievo* was the style most generally adopted in the land of obelisks and pyramids, a method possessing many advantages over the ordinary or *projecting* relief, and one that Mr. Bell thought should be employed more often at the present day. On this point he says:—

"Now, doubtless this mode was recommended in a degree to the Egyptians by its convenience as well as by the simplicity of its workmanship. For instance, the faces of an obelisk, or tomb, or temple, might be hewn down quite plain without any previous arrangement of projections left for the sculpture, the very subject of which might be left for after-consideration, as was evidently occasionally the case in Egyptian works.

"The ease and convenience that thus, in this respect, attached to the method then, would, of course, equally attach to it now. Take, for instance, the large granite forms of a bridge. These might be hewn with the greatest breadth and simplicity, and yet, afterwards, either before or after erection, the blocks which compose it might receive the decorative enhancement of incised relievos.

"One remarkable art quality also must not be overlooked in this incised method of relievo, viz. that while it finely decorates a surface it does not disturb its breadth, enough of the true original surface always remaining to assert that. Nor does it take away from the impression of solidity, but rather the contrary. Also, it does not injure the profile. You may recognise at once how the effect of an obelisk, for an instance, would be destroyed by any projecting relievo on its faces; how, in that case its grace and character would be lost at once, while, on the other, hand, any degree of incised enrichment is applicable to its faces, without any disturbance of the original contour. This would suggest that this mode is applicable also to columns of elegant proportions.

"Another advantage of this style of work is its enduring character, especially when worked in granite. There is nothing to knock off. In fact, it excels in endurance the other styles of relievo as much as the material excels other stone, as is illustrated by the endurance of various Egyptian works of ancient time, in which some of this incised relievo has stood exposed to the atmosphere for more than 3,000 years, without being materially injured."

With the principal sources of the granites used in this country, and the usual modes of working the stone, our readers are probably acquainted, but one more quotation on the subject of quarrying, may not be uninteresting:—

"In Egypt the blocks are said to have been greatly wrought on three sides in their native bed; the stone in front, above, below, and at each end, having been worked away, so as to leave them projecting, and attached only by one side to the rock. Then the process was also to cut, between it and the rock, holes at intervals. Into these holes were driven, quite tight, very dry small billets of wood, exactly fitting them, which, afterwards, being amply and continuously supplied with water, swelled by absorption, and burst off the block. This mode was formerly used in some of our own quarries.

"In India, a long block was in a similar way fashioned horizontally on its native bed, at last, in like manner, hanging to the side of it. But this was detached by a different process, the aid of fire being called in as well as water; as thus:—On the top surface, between the obelisk and the rock, a long deep groove was chiselled extending the whole length. This was kept full of fire — of live embers — at a great heat for some days, when all at once were these swept out and cold water poured in the whole length of the groove, when the sudden contraction split off the mass neatly from end to end.

"In Russia, a still different method was applied—that of frost, which was so ready at hand. When the huge columns for St. Isaac's Church had been similarly wrought in their native bed, holes were made all along their attachments, and filled with water, which, expanding in freezing, burst off the block. So you see that there are several ways in which this apparently difficult process may be simply effected. Practically, however, in the British quarries, when a large block is pretty near separation, and is left for a night, it frequently detaches itself, owing also, as is supposed, to some effect of change of temperature."

The suitability of granite for our public drinking-fountains was next discoursed on by Mr. Bell, who also dwelt upon the propriety of taking many specimens of British flowers and plants as art-models, naming, specially, the white and yellow water lilies (*Nymphæa alba, and N. lutea*), various ferns,—the tiny myosotis and the "lily of the vale," all beautiful in themselves, and capable of great development when employed as types for extended decoration.

The discussion ensuing upon the paper we have thus briefly noticed, drifted immediately, far away from art, into the less poetical considerations of the geological origin of granite, and the cost of working it. The meeting terminated its proceedings by an inspection of the various specimens, drawings, &c. exhibited, and by a vote of thanks to the author.

NOTICES OF BOOKS, PATENTS, &c.

1. *On the Sewage of Towns as it affects British Agriculture, by* Mr. Alderman Mechi.
2. *On the application of Town Sewage to a large Agricultural Area, comparing its Strength and Dilution with the ordinary Farm Manurial Resources, &c. &c. by* Mr. Alderman Mechi. (*Read at the Society of Arts.*)
3. *A Lecture on Sewerage, Delivered at Oxford, by* C. Daubeny, *M.D., F.R.S., Professor of Rural Economy.*

Unfortunately for readers and reviewers, the literature of London sewage, if we may so call it, offers but little that is novel. The authors all enlarge on the sin of wasting it, all insist on its immense value, only varying in their estimate by a few hundreds of thousands of pounds; almost all are agreed that the only way of utilising it is to employ it for the purpose of irrigation, and all make use of the same illustrations of the immense benefits derived from its use. Of the worth we imagine there cannot be two opinions. Dr. Hofmann some years ago likened it to the gold in sands of the Rhine — "its aggregate value must be immense, but no company has ever succeeded in raising the treasure." Mr. Austin, in his *Report on the means of Deodorizing and Utilizing the Sewage of Towns*, 1857, says that the minimum value of the sewage is represented by six shillings per head of the population per annum. "This looks," he adds, "a small sum in itself: let us see what it means in reality. It means 3000*l.* per annum for every 10,000 of the population. *It means an average annual rate of upwards of eighteen pence in the pound!* And the difference between this sum and the actual cost of getting this manure on the land means the amount of *direct* money loss from permitting this matter to pollute our rivers and injure our health." The money value, calculated from a long series of analyses by Messrs. Hofmann and Witt, was represented as much higher than this. They estimated it in fact at 1,385,540*l.* per annum. Mr. Mechi thinks it is worth 2,000,000*l.*

But the great question for our consideration is — How are these sums to be realised? On this it must be confessed we have not yet received much enlightenment. The report of Messrs. Hofmann and Witt was almost entirely negative. They had no hesitation in stating their conviction that the problem of recovering the valuable constituents of sewage, remains altogether unsolved; and they had only very faint hopes that the progress of chemical discovery would supply the means of so doing. They pressed the claims of the irrigation scheme, not because they were sanguine of its success, but because, of the numerous propositions which had been made for the profitable disposal of London sewage, it appeared to be the only one which deserved seriously to be entertained. Mr. Austin is in favour of a mixed system of separating the solid matter by a rough sort of filtration, to form cheap solid manure, and using the liquid part only for irrigating grass lands.

But before Mr. Austin's Report was published a government commission had been appointed "to inquire into the best mode of distributing the sewage of towns, and applying it to beneficial and profitable uses." A committee of five of these gentlemen visited and inspected all the sewage works in operation at the time (1857); a deputation made a trip to Milan, and in the following year they issued a "Preliminary Report." Two years have elapsed since the date of that Preliminary Report, and nothing more has yet been heard of the commission. Whether it is still sitting we do not know, nor is it, we imagine, of very much importance. There is nothing in the Preliminary Report which can lead us to hope that the subject will receive any great amount of elucidation at the hands of the commission. It merely repeated Mr. Austin's recommendation of a mixed system of precipitating the solid matters and using the liquid for irrigation, as circumstances, levels, localities, markets, &c. may render advisable.

It is in this state of the question that Mr. Mechi comes forward to support a gigantic scheme for distributing the sewage of London over a large space of country by carrying mains along the public roads, so that farmers shall only have to attach pipes to carry it all over their land. He proposes to raise a company with a capital of two millions, which shall construct the works and lay down the mains, and then distribute the sewage at the charge of one penny per ton within a radius of thirty miles! By an easy calculation Mr. Mechi arrives at the conclusion that the greater part of that penny would be profit on the undertaking. It does not lie exactly within our province, or we might point out to Mr. Mechi that within an area of thirty miles there are plenty of towns which might compete with London in the supply of

their own neighbourhood, and some other circumstances which might interfere with his calculations.

The indisposition of farmers in general to make use of the sewage he is perfectly aware of, and the paper read at the Society of Arts was intended "to rebut certain objections raised, and to dispel erroneous opinions that exist on this question." The answer to the first objection — that sewage is too much diluted to be beneficial, will show Mr. Mechi's way of answering objections. "The farmer's principal source of manure," he says, "is his live stock." He then goes on to show that the farmer has something less than two sheep per acre as a source of animal manure. Two sheep per acre would be equal in manurial results to two inhabitants of a town.

"Now let us see whether this manure of two sheep per acre gets more or less dilution than the excrements of two human beings residing in towns. The manure of two sheep, which is nearly all fluid (the dry matter being only $\frac{1}{18}$th), is spread over one acre of land. Taking the average of the kingdom the rain fall on this acre will be about 26 inches per annum, or 2626 tons. Thus the manure of each sheep is diluted with 1363 tons of water: but the excrement of each resident in towns only receives as follows:

Annually, as water supply . . .	30 tons
„ rain fall	50 „
	80 „

Thus proving unmistakeably that the much abused town sewage is in reality sixteen times less diluted, and consequently sixteen times stronger than that on which the farmers of England depend for the production of their crops."

To our minds Mr. Mechi has proved "unmistakeably," that when the diluted sewage of one individual is distributed over the acre, it gets sixteen times further diluted by the rain fall, just as the manure of each sheep does; or that the excrement of an individual when applied in the way Mr. Mechi recommends, gets diluted with 1443 tons of water.

It is in some such way as the above, we fear, that Mr. Mechi prepares the balance sheets which so confound farmers and puzzle accountants. In his published lecture he says that for the last six years his gain *as landlord and tenant* has been nearly 700*l.* per annum on his little farm of 170 acres. This looks an extraordinary result; but it is commonly said that Mr. Mechi, "*as landlord and tenant*" has *sunk* some 20,000*l.* on this little farm of 170 acres, for which sum 700*l.* per annum is poor interest for capital, to say nothing about profits on working the farm.

We have left ourselves scarcely space to notice Dr. Daubeny's cautious and thoughtful lecture, nor further to allude to the chemical part of the subject, than once more to press it earnestly on the attention of all practical chemists. "There is good ground for believing," say the government commissioners, "that the methods yet proposed for dealing with sewage are not the best that can be devised, and that further investigation will probably result in the discovery of processes more thoroughly equal to the suppression of the nuisance, and at the same time calculated to give more valuable products." In this belief we cannot help joining, and therefore strongly recommend the consideration of the subject to every chemist who is anxious for fame and fortune.

Treating Ores to obtain Metallic Oxides for Dyeing, Printing, and Painting. F. W. Emerson.

This patent was briefly alluded to in our last number; we shall now offer a few remarks upon it. We confess we should not take it up so much in detail, were it not that it has excited a great deal of attention, more especially among theoretical chemists who have long considered tungsten as belonging to those groups of metals which, like thorium vanadium, tellurium, and many others, are of extreme interest as regards their reactions and general properties, but apparently too rare to be made available in the arts. Tungsten has been looked upon by chemists for some time past as likely ere long to be removed from this reproach, and efforts have been made by several skilful chemists to apply the comparatively large quantities which are now being discovered to practical uses. Tungstate of soda has already been used as a mordant, and for the purpose of rendering fabrics non-inflammable; Mr. Emerson's patent is, more especially, for procuring colours for dyeing, printing, and painting.

The first thing to which his patent calls attention, and to which a chemist's notice would be attracted, whether placed first or last in the patent, is what the patentee considers a new metal, and accordingly, exercising the privilege of discoverers, gives to it the unfortunate name of chrolithineum. We say unfortunate name, because it is not only the longest name upon the list of metals, but the ugliest. We shall presently see the evidence upon which the existence of this new metal is based. Here are three points claimed in the invention:—

"It consists, firstly, in the separation of a metallic substance, which I believe to be entirely new, and which I propose to call chrolithineum, from the so-called ores of tungsten, such as wolfram, tunstate of lime, tungstic oxide and others, and the manufacture and application of its various salts to useful purposes in the arts, such as dyeing textile fabrics, painting on porcelain, and the production of paints and pigments.

"Secondly, in the manufacture and application of the so-called blue oxide of tungsten as a dyeing substance for textile fabrics, and as a paint or pigment.

"Thirdly, the production of paratungstate of alkali, metatungstate of alkali, isotungstate of alkali, and polytungstate of alkali, which may be used in the preparation of paints and pigments, and for dyeing textile fabrics, and other useful purposes, and the combination of paratungstic, metatungstic, isotungstic, and polytungstic acids with any suitable metallic oxide, or mixtures of metallic oxides as a base, such as the oxides of lead, zinc, barytes, lime and others, to form paints and pigments."

In order to obtain the salts or oxides of the new metal, the patentee fluxes the ores with an alkaline salt; but in place of doing this in an ordinary reverberatory furnace, by which the vapour would be lost, he conducts the operation in a retort of iron or fine clay, and conducts the volatile portion into a condensing apparatus.

To procure the metal from the oxide or salt, he reduces with coal, coke dust, or oil, tar, hydrogen, carburetted hydrogen, potassium or sodium.

To produce paints or pigments with chrolithineum, he takes the solution of a salt of it, either alone or mixed with the salt of any other metallic oxide that does not cause a precipitate, and adds the salt of any other metallic salt which *will* cause a precipitate, with or without the addition of any vegetable or animal tinctorial matter. As an example, the patentee cites a process with bichromate of potash, which is exactly the same as that for preparing chromate of lead, except that for a solution of lead he substitutes a solution of chrolithineum. This process for producing a yellow on a textile fabric is also precisely that for dyeing yellow with lead and bichromate of potash. In fact all the evidence given in the patent leads us to believe that chrolithineum is lead, which has been carried over in the distillation in the way that we know it is often carried into the flues of lead reducing furnaces. Of course we do not say that Mr. Emerson has not had the good fortune to discover a new metal, but the patent before us does not prove the fact. If, however, the patentee has been so happy, he may indeed be proud of so brilliant and unlooked for a result. Moreover, as he gets the new metal from wolfram, tungstate of lime, tungstic oxide, it is plain that Scheele, Klaproth, Vauquelin, Berzelius, Wöhler, Malaguti, Laurent and others, have all erred fearfully in their analyses of the ores and salts of tungsten, and have moreover allowed a most brilliant discovery to slip through their fingers.

The patentee prepares his alkaline tungstates, paratungstates, metatungstates, isotungstates, and polystungstates by Laurent's methods, he then claims the salts of these acids

with all the metallic oxides as paints or pigments. He does not, however, state what colours he obtains, and with the metals which give colourless solutions we believe only white precipitates are obtained; but the following are some of the coloured tungstates which are commonly known:

Tungstate of	molybdenum	dark purple
"	chromium	green
"	vanadium	brownish yellow
"	uranous oxide	brown
"	uranic oxide	light yellow
"	cadmium	white, but reddish when gently heated, and bluish black if heated to redness.
"	tin	yellow
"	ferrous oxide	light brown
"	ferric oxide	cinnamon coloured
"	cobalt	violet
"	nickel	light green
"	copper	"
"	mercurous oxide	yellow
"	mercuric oxide	yellow or red
"	silver	white, but brown when gently heated.

From the extreme scantiness of our knowledge upon the compounds of tungsten with the metals, it becomes probable that the patentee will find some valuable pigment among them.

The patent includes the use of the tungstates for dyeing. In using the tungstates, he takes a solution and boils the fabric with it, and then passes the prepared cloth through decoctions of the dye-woods, Persian berries, cochineal, &c. He does not mention the colours obtained, but the subject is interesting, and the patent may, one day, turn out very valuable, if any of the colours are good.

Perhaps the most interesting portion of the patent is where the formation of the blue oxide in tissues is claimed. He boils the yarn, &c. with an alkaline tungstate, and after drying, immerses in dilute muriatic, sulphuric, or acetic acids, and then deoxidises with metallic tin or zinc. We should much like to see some cloth dyed in this way. To sum up, there is much that may be very valuable in this patent, but the information in it as to the nature of the dyes and colours obtained is too vague.

CORRESPONDENCE.

Building Stones.

To the Editor of the Chemical News.

Sir,—I was unwilling to lengthen still further the protracted discussion on Mr. Burnell's paper, but I will now crave permission to say a few words concerning that part of it relating to "salt efflorescences." In the first place the terms "saltpetering" and "nitrification," are apt to suggest to a casual hearer that the substance in question is mainly composed of nitre, or more correctly nitrate of potassium, whereas such is very seldom the case; in fact it is quite the exception instead of being the rule. I have now before me some notes of 37 specimens of "salt" collected from the surfaces of various building materials. Of these 31 contained only sulphate of sodium (with inconsiderable traces of other salts); 3 were mainly composed of the same salt, but also contained sulphates of magnesium and aluminium; 2 samples consisted of sulphate of sodium, together with various phosphates and nitrates, the latter (generally nitrates of sodium and calcium) never exceeding 18 per cent. of the whole. The last specimen was made up of the sulphates of sodium and potassium, with a small amount of nitrates, and a notable quantity of common salt, &c.; this latter ingredient being derived, I imagine, from sea-spray, as the sample was found in a vault at the old castle of Mont Orgueil, Jersey. For all practical purposes I think that sulphate of sodium may be taken as the chief component of those "salt" formations, so destructive to the architecture of this country; and in all building materials, therefore, whether of natural or artificial origin, the absence of this substance should be satisfactorily proved before they are employed for any important work. If due precautions had been taken by the Crystal Palace Company in the selection of their materials, and if surface-water had never been used there for mixing mortars, cements, &c. I feel assured that the salt "efflorescences" apparent in the Pompeian, Byzantine, and other courts, to the disfigurement alike of classical decoration and visitors' coat sleeves, would have been far less injurious, if, indeed, they had not been altogether avoided.

With regard to the preventive means, I can add but little to the mass of information already obtained; but I cannot help denouncing the too free use of resinous, oleaginous, or tarry matters, as my own experiments have shown me that, in the event of fire, the walls of a building treated with such substances would inflame the moment their temperature was raised to about 200°. Still, where a building is to be erected upon a soil known to be impregnated with various salts, the writer's plan of "insulation,"[1] in which the upward percolation of moisture, if the expression is allowable, is prevented by a seam of asphalte laid on every wall, when at a height of from two to four feet from the ground, may be employed with safety and advantage. To the general efficiency of silicate of calcium, or, still better, of aluminium, I can also bear testimony.

In reply to an observation of Professor Ansted's, I may here remark that I have observed silicate of calcium in a partly crystalline condition, when its formation has been very slow, but in this state it is certainly very rare. In relation to curative processes, I am decidedly of opinion that no universal system can be recommended. The plan adopted should always be that most suited to the requirements of each particular case. Where, as generally happens, the efflorescence consists chiefly of the sulphate of sodium or magnesium, a weak solution of chloride of barium may be applied with great advantage, as the original "salt" is then destroyed, sulphate of barium and chloride of sodium (or magnesium) being formed. The first is perfectly insoluble, and the latter, which appears to have little or no action upon building materials, soon gets washed away. This solution, and also one of shell-lac in ordinary borax, was kindly tried for me at the Crystal Palace, by gentlemen connected with the fine arts department, more than three years ago, as far as I can now learn, with entire success. Sulphate of ammonium has, according to my experiments, no injurious effect on buildings until it meets with substances capable of converting it into the corresponding sodium salt; and I consider that its action may be disregarded practically, as its presence in the atmosphere is quite exceptional. Sulphurous acid, also, either free or in combination with ammonia, I believe to have rather a preservative influence than otherwise, as it is never present in sufficient quantity to cause an efflorescence of sulphites; and its compounds with lime, alumina, &c. are very insoluble. It is very probable that the theory of osmosis has been endowed by many with far more important functions in relation to building materials than it really possesses, for, granting that stone has a large amount of air condensed within it when first quarried, the process of diffusion, resulting from occasional and minute differences in the external atmosphere, must proceed but very slowly under the retarding influences of damp and a low temperature. In common with many others, I differ entirely from Mr. Burnell when he designates as "obscure" that branch of chemical science relating to the phenomenon of "salification," as I prefer to call it.—I am, &c.

Wentworth L. Scott.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

On some Metallic Selenides, by G. Little.[1]—*Selenide of Nickel*, Ni Se, is obtained by heating thin plates of nickel in the vapour of selenium. It is silver white, has a metallic lustre, is unaffected by the atmosphere, but when heated gives off the selenium. It is not attacked by water, dilute or concentrated hydrochloric acid, but is perfectly dissolved by nitric acid and aqua regia. It melts at a strong red heat, and on cooling assumes a regular crystalline appearance; it is brittle, and gives an uneven fracture. The sp. gr. is 8·46. When fused with borax a beautiful golden yellow mass with a striated surface is obtained. It contains 43·13 per cent. of nickel.

Selenide of Cobalt, Co Se, is formed by the action of the vapour of selenium on cobalt in an atmosphere of hydrogen. Seleniuretted hydrogen is formed, part of which is decomposed by the cobalt and part of which escapes. Selenide of cobalt melts at a strong red heat. Fused with borax it gives a yellow crystalline metallic mass. It contains 42·31 per cent. of cobalt.

Selenide of Iron, Fe_2Se_3, containing 32·15 per cent. of iron, the author obtained by heating iron wire in the vapour of selenium. The product was fused with borax in a hessian crucible, and a greyish yellow metallic mass was obtained, which was easily pulverised, which soon changed in the air, and which had a sp. gr. of 6·38. With hydrochloric acid it gave chloride of iron. Seleniuretted hydrogen was developed with diluted nitric acid. It dissolved in strong nitric acid, forming a yellow liquid.

Selenide of Cadmium, Cd Se, which contains 56·76 per cent. of cadmium, is a golden yellow, lustrous crystalline substance which melted with borax, gave a greyish black lamellar, crystalline easily powdered mass, with the sp. gr. 8·789.

Selenide of Tin, $Sn Se_2$, is formed by precipitating chloride of tin with hydroselenic acid. The vapour of selenium unites with melted tin to form a tin white mass, having a metallic lustre, and giving a conchoidal fracture. Its sp. gr. is 5·133. It melts easily, is not attacked by hydrochloric acid, is quickly decomposed by nitric acid, and soon dissolves in aqua regia. It contains 43·71 per cent. of tin.

Selenide of Bismuth, $Se Bi_2$, is not attacked by hydrochloric acid, is only slightly soluble in dilute nitric acid; but is quickly and perfectly dissolved by strong nitric acid and aqua regia. The sp. gr. is 7·406, and its composition approaches the formula $Bi Se_3$. It contains 66·79 per cent. of bismuth.

Selenide of Copper, Cu Se, may be made by precipitating the sulphate of copper with hydroselenic acid; or in the dry way by passing selenium vapour over heated copper foil. In the latter way a greenish black crystalline mass is formed with the sp. gr. 6·655 and the composition Cu Se. It contains 44·03 per cent. of copper.

Selenide of Mercury, $Hg_2 Se$, obtained by heating selenium and mercury together and allowing the product to sublime, forms purple or violet coloured lustrous crystals which have the sp. gr. 8·377. The compound contains 83·76 per cent. of mercury.

Selenide of Lead, properly prepared, has nearly the formula Pb Se, and the sp. gr. 8·154. It contains 71 per cent. of lead.

Selenide of Arsenicum, $As Se_3$, obtained by heating arsenicum with melted selenium, is a shining metallic, friable mass, which is easily reduced to a black powder. The sp. gr. is 4·752. It contains 57 per cent. of arsenicum to 43·03 of selenium. (These numbers have, perhaps, been changed by mistake: to form $As Se_3$ 38·94 per cent. of arsenicum and 61·06 of selenium are necessary.)

II. ORGANIC CHEMISTRY.

Strychnia and Brucia.—M. Stahlschmidt publishes a long memoir on these bodies[2], in which he shows that when an equivalent of their hydrogen is replaced by an equivalent of methyl (C_2H_3) the new compound is quite innocuous. The author proved it by experiments on a rabbit, which suffered no ill effects from the administration of the methylated alkaloid, but died in five minutes after the $\frac{2}{100}$th of a gramme of pure strychnia had been placed upon its tongue.

Methyl-brucia behaves in exactly the same way as methyl-strychnia. M. Nickles[3] points out the fact that substitution does not in every case so completely change the physiological properties of the alkaloids, for chlorinated strychnia is as poisonous as the original strychnia. In these cases however the change has been occasioned by methyl, and it is curious to know that hydrocyanic acid in combination with methyl is perfectly inoffensive.

The methylated bases are prepared by the ordinary processes. The alkaloid in fine powder is placed in contact with iodide of methyl which combines with it, forming a new compound which is the iodide of base substituted:

$$C_{44}H_{24}N_2O_4I \text{ or } N\left\{\begin{matrix}C_{42}H_{20}N_2O_4\\C_2H_3\\H\end{matrix}\right\}I.$$

This iodide is very soluble in warm water, and slightly so in cold. It is decomposed by the salts of silver, which fix the acid and form iodide of silver. It is not volatile. In contact with oxide of silver and a little water it yields the free base—hydrate of methyl-strychine; which however may be obtained more easily by decomposing the sulphate with baryta water. The liquid is coloured violet at first, but long yellowish crystals soon appear, which do not change when exposed to the air, and contain 16 or 17 per cent. water. This is the hydrated base. It is very soluble in water and in alcohol, but insoluble in ether. It displaces the principal metallic oxides from their combinations, and is coloured brown when treated with peroxide of lead or bichromate of potash and sulphuric acid. The author has further studied the various compounds this base forms with acids.

Methyl-brucine is obtained like the preceding, but it is difficult to isolate the hydrated base. It forms compounds in every respect similar to those of methyl-strychnine. The hydriodrate of methyl-brucine, $C_{46}H_{29}N_2O_8 + I$, crystallises in brilliant lamellæ. From what precedes the authors conclude that strychnia and brucia are two bases of the same class as the ammonias.

III. CHEMICAL ANALYSIS.

Detection of Protoxide of Copper in the Presence of Binoxide.—Protochloride of copper reduces sesquichloride of iron even in the cold, and such a solution is not coloured red by the sulphocyanide of potassium; on the contrary, it decolorises a solution prepared with a salt of the sesquioxide of iron and a sulphocyanide. These reactions do not take place in the presence of albumen which precipitates the ferric salts. In such a case Schiff[4] employs with success a solution of iodic acid and starch. The least trace of the protoxide of copper is shown by reduction of the iodic acid, and the production of the blue iodide of starch. When the liquid is alkaline it must be neutralised with pure hydrochloric acid.

Similar reductions take place with chromic, molybdic, and tungstic acids. With protoxide of copper dissolved in ammonia, chromic acid is reduced to the green oxide, tungstic acid to the green sesquioxide, and molybdate of ammonia to the blue oxide. Schiff prefers iodic acid to these reagents, because it is easily procured, and because albuminous liquids do not interfere with the action.

IV. TECHNICAL CHEMISTRY.

Calcium.—A ready way of procuring calcium has been discovered by M. Caron.[5] He heats in an ordinary furnace a mixture of fused chlorine of calcium in powder, 400 parts

[1] *Annal. der Chem. und Pharm.* Bd. cxii. s. 211.

[4] *Annal. der Chem. und Pharm.* Bd. cxii. s. 211.
[5] *Comptes-Rendus.*

of granulated zinc, and 100 parts of sodium — using as great a heat as possible, but preventing the volatilisation of the zinc. An alloy of calcium and zinc is found in the crucible, whilst the preparation is finished, which is then heated in a carbon crucible until all the zinc is driven off. The author hopes to procure barium and strontium in the same way.

SCIENTIFIC NOTES AND QUERIES.

Mulder's Process for Determining the Amount of Alcohol in Wines and other Alcoholic Mixtures. — Sir, — Your correspondent *E. G.* (Chemical News, No. 9, p. 108) so unjustly condemns as incorrect the useful method of Mulder for determining the amount of alcohol in wines and other alcoholic fluids, that it is but fair to set your readers right upon the subject. In this method, of which it will be recollected that an example was given in No. 3, p. 36, the sp. gr. of the alcoholic fluid to be examined is taken, and half being then evaporated away the residue is increased with water to its original volume. The sp. gr. of this mixture being then taken, the latter sp. gr. is deducted from the former, and the result is the sp. gr. of the alcohol and water as they existed in the fluid. *E. G.* sets out with the assertion that the result obtained in the working of the example is erroneous :

Sp. gr. of the wine	0·9953
Sp. gr. of the mixture	1·0080
	0·9873

"9873," he says, "is not the difference between 1·0080 and 0·9953 : the difference is ·0127." Now it is evident that if 0·9953 were subtracted from 1·0080 the difference would be ·0127, but then the reverse of this operation is distinctly indicated and the difference is thus clearly 0·9873. *E. G.* then gives a rule for the correct working of the problem, which I deduce from his formula to be this :—The specific gravity of the alcohol and water evaporated ; that is, forming half the volume of the fluid is obtained by subtracting twice the difference between the specific gravity of the wine and that of the mixture from 1000. The example in question would according to this rule be worked thus :

1·0080 − 0·9953 = ·0127
·0127 × 2 = ·0254
1000 − ·0254 = ·9746 = the sp. gr. of half the original volume.

According to Mulder's working the specific gravity is ·9873, but then it must be remembered that this latter is the specific gravity of the alcohol and water *as they existed in the wine*, and not in half its volume. The result obtained by *E. G.* may thus be shown to exactly coincide with that given by Mulder, for if ·9746 be increased by 1, and this divided by 2, the specific gravity of the alcohol and water as they exist in the wine is obtained :

$$\frac{1{\cdot}9746}{2} = {\cdot}9873.$$

Or if the multiplication of the difference between the specific gravities be neglected, the same result will be arrived at : 1000 − 0·0127 = ·9873. The methods of Mulder and of *E. G.* give, therefore, precisely similar results, if the volume of fluid whose specific gravity is ascertained be always borne in mind. I may add that, from having repeatedly compared the results obtained by the ordinary mode of distillation with this method, I am perfectly satisfied of its correctness, while the great facility and rapidity with which the operation is performed, recommend it above every other with which I am acquainted.—*H. Napier Draper, F.C.S.*

LABORATORY MEMORANDA.

Apparatus for keeping a Liquid at a constant Level.—Sir,—Having recently been engaged in some experiments on solutions requiring the loss by evaporation to be made up from time to time, I was induced to construct an apparatus which should perform this duty without the necessity of continual supervision. Thinking the arrangement may be of use to some of your readers I will endeavour to describe it. A flask is provided to contain the supply of water or other liquid, to which is fitted a cork pierced with two holes ; into each of these holes is inserted a tube bent twice at right angles in such a manner as to form a syphon. One of these tubes (which I will call the first) descends to the bottom of the flask, the second tube terminating in the top. All the joints must be made airtight, and it is then ready for use in the following manner : the flask and first tube is filled with water, and the thumb being placed over the orifice, the two tubes are placed in the vessel containing the solution in such a manner that the second tube shall just reach the level it is desired the water shall keep. The thumb being now removed the water will flow into the vessel until the orifice of the second tube is covered, when the flow of water will stop until by evaporation the orifice is again exposed, when the syphon will again act. The apparatus will continue to act in this manner until the liquid attains the same level in both vessels. It may be filled either by a third tube, which must be capable of being closed airtight at pleasure, or by inverting the apparatus and inserting a funnel into one of the tubes. By means of a perforated cork the apparatus may be fitted to a retort or gas apparatus.—*John Tillman.*

MISCELLANEOUS.

Clarifying Coal Oils. — Messrs. Dumoulin and Cotelle have been making a series of experiments with a view of rendering heavy oils suitable for ordinary lighting purposes, and have succeeded in producing a magnificent light, free from smoke and smell, and adapted in all respects for burning in a room. The following is their process :—In a close vessel are placed 100 lbs. of crude coal oil, 25 quarts of water, 1 lb. of chloride of lime, 1 lbs. of soda, and half a pound of oxide of manganese. The mixture is violently agitated and allowed to rest for 24 hours, when the clear oil is decanted and distilled. The 100 lbs. of coal oil are to be mixed with 25 lbs. of resin oil ; this is one of the principal points in the manipulation, it removes the gummy parts from the oil and renders them inodorous. The distillation spoken of may terminate the process, or the oils may be distilled before they are defæcated and precipitated.—*Le Génie Industriel.*

Transparent Ivory. — The process for making ivory transparent and flexible is simply immersion in liquid phosphoric acid, and the change which it undergoes is owing to a partial neutralisation of the basic phosphate of lime of which it principally consists. The ivory is cut in pieces not thicker than the twentieth part of an inch, and placed in phosphoric acid of a specific gravity of 1·131, until it has become transparent, when it is taken from the bath, washed in water, and dried with a clean linen cloth. It becomes dry in the air without the application of heat, and softens again under warm water.—*Druggists' Circular.*

ANSWERS TO CORRESPONDENTS.

*** In publishing letters from our correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

Selenium.—1. No. 2. No. But you must not call yourself a *pharmaceutical* chemist.

A Chemical Student.—Enter at the College of Chemistry or some other laboratory if possible. If not get some book on analysis and work straight through it at home.

Enterarmiá.—1. The ointment will keep well in cold weather, but the consistence will necessarily vary somewhat with the temperature. In the case of the clarified butter at 9*d.* per lb. is our correspondent certain that the whole of the mercurial solution was mixed by the "occasional" stirring ? 2. The easiest way to separate cadmium from zinc ore is to dissolve in sulphuric acid, supersaturate with the acid and precipitate with sulphuretted hydrogen. The sulphide of cadmium is then reduced and distilled.

Your Subscriber.—No ; it is not however "carbonising," but the escape, or efflorescence, of the water of crystallisation. Faraday says that crystals having no part of their surface broken, and carefully preserved from external violence, remain perfect.

A Subscriber.—1, A mixture of the best ivory black and spirit varnish carefully applied. 2. We do not know of any.

THE CHEMICAL NEWS.

VOL. I. No. 17.—March 31, 1860.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Remarks upon the various Methods usually adopted for the Separation of the Alkalies from the Bases with which they are generally associated in Soils, Minerals, &c. by FREDERICK FIELD.

THE separation of potash and soda from other metallic oxides, and particularly that of magnesium has always been considered a very delicate and somewhat difficult matter in chemical analysis. It is needless to observe that in the investigation of soils, minerals, glass, and some metallurgic products, such as slags, &c. great importance should be attached to their correct estimation; and although many excellent processes have been devised, it can scarcely be denied that at the best chemists must consider the determination of the alkalies as a responsible, and at times not a very satisfactory affair, owing to the comparatively minute proportions in which they generally exist, and the number of operations the substance containing them has to undergo before their complete elimination.

It is intended in the following remarks to recapitulate as briefly as possible some of the methods usually adopted, together with their attendant advantages and disadvantages.

1. *Fusion of the substance with hydrate of baryta.* A certain quantity of the mineral or other substance to be analysed is heated to bright redness with about four times its weight of hydrate of baryta in a platinum crucible for nearly an hour; the mass is not entirely fused, but agglomerated, and if the heat has not been too elevated, the contents on cooling may frequently be removed from the crucible by a slight pressure on its sides and a little skilful manipulation. When the temperature has been excessive, the mass is difficult of removal, and the platinum is acted upon by the baryta, not only deteriorating the crucible, but causing a loss of potash, as by subsequent digestion in hydrochloric acid, the double chloride of platinum and potassium is liable to be formed, which remains with the silica after evaporation to dryness. Independently of this, the solution of the compound in the crucible is very tedious, from the great insolubility of chloride of barium in hydrochloric acid, a layer of this salt forming upon the surface of the undecomposed carbonate, and retarding the action of the acid. The preliminary removal of the contents of the crucible is therefore of some importance, provided it can be effected without loss. Dilute hydrochloric acid is added, and after complete solution the whole is evaporated to dryness. On removal of the silica by filtration, hydrate of baryta is added until the solution is decidedly alkaline, the precipitate filtered off, and carbonate of ammonia, mixed with free ammonia, is added in excess; the liquid is heated, allowed to stand for some time, and filtered with the usual necessary washings, the filtrate evaporated to dryness, and ignited. The excess of ammoniacal salts is volatilised, and the alkalies estimated in the usual manner. I have always found a considerable difficulty in this process, viz. the entire separation of the baryta by means of carbonate of ammonia. Even after boiling the strongly alkaline liquid produced by adding an excess of this reagent, baryta is recognised in the filtrate, and has again to be separated. As it is advisable to obtain the alkalies in union with hydrochloric acid for the separation of the potash from the soda by means of chloride of platinum, the simple addition of sulphuric acid for the removal of the baryta is inadmissible.

The alkaline chlorides together with the excess of carbonate of ammonia, and carbonate of baryta must be ignited, weighed, and the latter collected, estimated and deducted from the weights of the mixed carbonates after ignition.

There is no doubt, I believe, that carbonate of baryta is soluble to a slight extent in solutions of ammoniacal salts, more especially in chloride of ammonium. Even the sulphate is very slightly soluble in both nitrate of ammonia and chloride of ammonium.

Perhaps a more advisable method than the preceding, and one adopted many years ago by Berzelius, consists (when the alkalies and other bases exist as sulphates), in decomposing by acetate of baryta, filtering and igniting. The alkaline carbonates can then be separated from the rest by the addition of boiling water.

By this means ammoniacal salts may be altogether avoided. In the filtrate from the silica, dilute sulphuric acid is added, and the baryta entirely precipitated, whilst all the other bases remain in solution as sulphates; the addition of acetate of baryta converts them into acetates, which by ignition are reduced to carbonates (in the case of iron, to peroxide), and the alkalies separated by solution in water.

Lime, magnesia, and the alkalies may be determined in a soil or mineral product without the necessity of two fusions, as is usually the case, by adopting either one of the two following methods.

To the filtrate from the silica sulphuric acid is added, so as to precipitate nearly all the baryta, yet leaving the latter in slight excess; the sulphate is filtered off, and oxalate of ammonia added, which throws down the lime and the remaining small quantity of baryta. After washing, the precipitate is ignited with the usual precautions, and weighed; redissolved in hydrochloric acid, sulphuric acid added, the precipitate thoroughly washed, dried, ignited, the weight of the baryta calculated from the sulphate, and deducted as carbonate, from its admixture with the carbonate of lime. The magnesia and alkalies according to Heintz [1] may be separated as follows. To the filtrates from the oxalates of lime and baryta, phosphate of ammonia is added, which precipitates the whole of the magnesia. After filtration the phosphoric acid is precipitated by a solution of nitrate or acetate of lead, and the excess of lead removed by boiling with carbonate of ammonia and ammonia. After filtration, the alkalies with the ammoniacal solution are

[1] *Q. Journ. Chem. Soc.* vol. i.

evaporated, ignited, and the former estimated in the usual manner.

Sonnerschein's method [1] may also be advantageously adopted under similar circumstances.

After removal of the lime, the filtrate is evaporated to dryness, and gently ignited. Water is poured upon the dry mass when cool, and it is then boiled with carbonate of silver until the liquid has a strong alkaline reaction. After about ten minutes boiling the decomposition is generally complete. The alkalies with a trace of silver are in the filtrate, and the whole of the magnesia with the precipitate. A few drops of hydrochloric acid remove all the silver, and the alkalies can be readily estimated. The addition of the same acid forms an insoluble chloride with the precipitate, dissolving the magnesia, which can be determined as pyrophosphate, by addition of phosphate of soda in its ammoniacal solution.

When, however, the alkalies and magnesia are together as sulphates, the following method as suggested by Ebelman, may be adopted. That chemist having found considerable mechanical difficulties in filtering the sulphate of baryta, formed by the decomposition of the acetate of that base, proposed heating the sulphates of magnesia, potash, and soda, with carbonate of baryta suspended in water. This plan was not effectual, as the decomposition was incomplete, and sulphuric acid was always found in solution.[2] If the liquid, however, be acted on simultaneously by carbonate of baryta and a current of carbonic acid, a bicarbonate of baryta is formed, and consequently no trace of sulphuric acid can exist. The alkalies also are converted into bicarbonates, together with a portion of magnesia. On filtering, evaporating to dryness, and digestion in water, the alkalies are dissolved, and the magnesia can be separated from the baryta by means of sulphuric acid.

There are still simpler methods for the separation of magnesia from the alkalies, of which mention will be made in the next number.

(To be continued.)

On the Formation of Tartaric Acid from Sugar of Milk and Gum, by J. VON LIEBIG.[3]

WHEN a mixture of one part of sugar of milk, two and a half parts of nitric acid, sp. gr. 1·32, and two and a half parts of water, is moderately heated, carbonic acid and gaseous products of the decomposition of nitric acid are disengaged, and there separates, after continuing the heat for some time, a thick white magma of mucic acid. Diluted with an equal volume of water, and filtered from the mucic acid, the liquid obtained yields a fresh portion of mucic acid on being again heated with one fourth of the nitric acid before employed. The whole of the mucic acid obtained amounts to about 33 per cent. of the sugar of milk. It follows that the greater part of the milk sugar must have escaped in the form of the gaseous products of oxidation, or be contained in the acid mother liquor, from which the mucic acid has been deposited. This liquid has a yellowish colour, and when concentrated by evaporation yields a thick acid syrup, which frequently under 100° becomes at first brown and then black. When the mother liquor, from the mucic acid, and the washings are mixed and boiled, carbonic acid and nitric oxide are disengaged, and the liquid becomes dark brown; but this last effect may be prevented by the addition from time to time of more nitric acid. After continuing the boiling for 18 or 24 hours, the liquid no longer turns brown on neutralising with potash. At this time it contains a large proportion of tartaric acid. It is now concentrated by a gentle heat, and divided into two parts: one is saturated with potash, and the two are then poured together and allowed to stand, when crystals of bitartrate of potash are deposited. These are sometimes mixed with needle-like crystals of saccharate of potash, which, being more soluble than the bitartrate, may be easily separated by dissolving the two in as small a quantity of boiling water as possible, and quickly cooling the solution. In this way the bitartrate is separated in the form of shining crystalline granules. By standing longer, the mother liquor yields the fine needle-like crystals of the saccharate of potash.

Two analyses of the artificially formed bitartrate gave the following results:—

	I.	II.	Calculation $C_8H_5KO_{12}$
Potash . .	24·5	24·3	25·06
Tartaric acid . .	75·5	75·7	74·94
	100·0	100·0	100·00

By adding nitrate of silver to the neutral potash salt, a white precipitate is thrown down, which quickly turns black in the light. On igniting the dry precipitate, 59 per cent. of metallic silver is left behind.

By neutralising the acid potash salt with soda, and slowly evaporating the solution, very beautifully formed crystals of Rochelle salt are obtained. After digesting the acid potash salt with antimonic oxide, well defined crystals of tartar emetic are deposited.

After these results, we can have no doubt of the formation of tartaric acid by the oxidation of milk sugar. It is also obtained when gum arabic is treated with nitric acid in the same way.

Besides mucic, saccharic, and tartaric acids, some oxalic acid is formed. The saccharic acid is in largest proportion immediately after the separation of the mucic acid; but by longer boiling with fresh additions of nitric acid it becomes decomposed, and the amount of tartaric acid in the residue increases.

A long illness has prevented Liebig from carrying out a series of experiments to decide the question whether the tartaric and saccharic acids are formed simultaneously, or first saccharic and then tartaric acid. He conjectures, however, that the latter is the fact—that the tartaric is formed from the saccharic acid.

From grape and cane sugar Liebig could not obtain tartaric acid, but as a small per centage of saccharic acid was formed from both, he believes the reason of his failure was the small quantities operated on.

On subtracting the formula of tartaric from that of saccharic acid, there remains a body with the composition of the carbohydrates:—

Saccharic acid . . .	$C_{12}H_{10}O_{16}$
Tartaric acid	$C_8\ H_6\ O_{12}$
	$C_4\ H_4\ O_4$

The elements of the last subtracted from tartaric acid leave oxalic acid:—

Tartaric acid	$C_8H_6O_{12}$
Carbohydrates . . .	$C_4H_4O_4$
Oxalic acid	$C_4H_2O_8$

---

[1] *Poggendorff's Annalen*, lxxiv. p. 313, and *Chem. Gaz.* vol. vi. p. 284.

[2] The sulphates of the alkalies, as is well known, are not decomposed to any great extent by carbonate of baryta when their solutions are heated. They are however completely decomposed in the cold. A warm solution of sulphate of magnesia is, on the contrary, rapidly and entirely decomposed by carbonate of baryta, although the decomposition is tedious at ordinary temperatures.—F. FIELD.

[3] *Annalen der Chemie und Pharmacie*, Bd. cxiii. s. 1.

Liebig believes that oxalic acid is the first acid product formed in a plant from carbonic acid, and that tartaric and malic acids are derived from oxalic. By exchanging two equivalents of oxygen for two of hydrogen, oxalic acid becomes malic; by exchanging four of oxygen for four of hydrogen, it produces aldehyde. Malic acid therefore may be considered as oxalic acid half changed into aldehyde.

To become tartaric acid, malic acid has only to fix two equivalents of oxygen:—

Malic acid	$C_8H_6O_{10}$
Tartaric acid	$C_8H_6O_{12}$

Tartaric acid then is only a product of the oxidation of malic acid; and this explains the constant presence of malic acid in unripe grapes.

TECHNICAL CHEMISTRY.

On a new Mode of Preparing Calcium, by M. H. Caron.[1]

Last year I had the honour to present to the Academy a new process for reducing the chlorides of calcium, barium, and strontium, and obtaining these metals alloyed with others, such as lead, tin, antimony, and bismuth. At that time I had not been able to separate the alkaline metal from these alloys; but since I have resumed my researches I have been able to isolate calcium. The following is the proceeding I have adopted. I make a mixture of 300 parts of fused chloride of calcium in powder with 400 of finely granulated distilled zinc, and 100 parts of sodium in small pieces. The whole is placed in a crucible and heated to redness in an ordinary furnace. At first the action is very feeble; but after some time we see zinc flames issue from the crucible. The heat must now be moderated to prevent the volatilisation of the zinc, but at the same time it must be maintained as high as possible. This is the most delicate part of the operation, and it requires the greatest care to arrive at a satisfactory result.

When the crucible has remained in this state for a quarter of a hour it may be withdrawn from the fire; and after cooling there will be found at the bottom a metallic button, very brittle, showing a brilliant fracture, and sometimes crystallised on the outside in prisms with square bases. It generally contains from 10 to 15 per cent. of calcium.

This alloy of zinc and calcium is scarcely acted on by water, especially at the ordinary temperature: oxalic and sulphuric acids have but a feeble action on it, in consequence of the insolubility of the salts produced; hydrochloric and nitric acids on the contrary rapidly dissolve it.

To procure the calcium from this alloy it is only necessary to put it into a coke crucible, and drive off the zinc by heat. It must be placed in the crucible in pieces as large as possible, or the calcium collects with difficulty. The alloy ought not to contain sodium (which will happen when the operation has been badly conducted) or the crucible cracks and the calcium is obtained badly aggregated and only in very small quantity. The alloy cannot be distilled either in lime or ordinary crucibles.

When the above precautions have been observed a button of calcium is obtained, only contaminated with the foreign metals which were originally contained in the zinc, or matters which may have been derived from the crucible.

The calcium I have so procured always contains traces of iron, and always has a brass-yellow colour when recently scratched. I have found its density to be 1·6 or 1·8, but the numbers are necessarily too high in consequence of the iron which it contains.

It is not sensibly volatile alone, but the zinc with which it is alloyed, in distilling, carries over a small quantity. In contact with moist air it breaks up like ordinary lime, leaving a greyish powder a little reddened by the iron. When enclosed in a well-dried bottle it keeps well, assuming, however, almost immediately a grey tint, which completely destroys the metallic appearance of it.

It burns with difficulty in the blowpipe flame because of the covering of lime immediately formed. The combustion of its filings gives rise to red sparks of remarkable beauty. No fumes are disengaged when it burns, which goes to prove that it is not volatile at the temperature of its combustion.

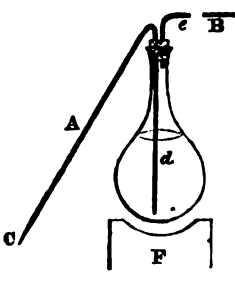
Before terminating the communication it is necessary to indicate one precaution which is indispensable in order to obtain the calcium pure. If commercial zinc be employed, however pure it may be, it always contains lead and iron, which are collected in the button in large proportion, because of the quantity of zinc with which the calcium is alloyed. And not only do we find the lead and iron contained in the volatilised zinc, but some zinc itself which the lead and iron retain and make it impossible to drive off. With the zinc of commerce I obtained a button of calcium containing:

Calcium	78
Lead	9
Zinc	11
Iron	2
	100

It is necessary therefore to employ distilled zinc, and then the calcium is obtained pure, or at most containing but traces of iron from the crucible.

Self-acting Wash-bottle. By Thomas Salter, *F.C.S.*

The following simple modification of an ordinary wash-bottle is convenient in those cases where a continuous supply of water is desired, whether hot or cold, in a thin stream or a succession of drops; and where the passage of the liquid through the filter is sufficiently rapid. The shorter limb *d* of the syphon-tube A, drawn out to a point at *c*, passes through the cork nearly to the bottom of the flask, which is filled up to the neck. By blowing air through *e*, the water is forced through A out at *c*, whence it will afterwards continue to issue of itself. The supply can be at once stopped by sucking air through *e*. To prevent the flask, *as it empties*, being tipped over by the weight of the syphon-tube, a block of wood hollowed in the middle (F) is useful as a stand.



In order to obtain a succession of drops, a short piece

[1] From the *Comptes-Rendus*, t. l. p. 547.—In our last number we gave a short abstract of this process, to-day we give the communication at length.

of tubing, drawn to a fine point at one end, has tightly rammed into it some cotton wool (B), and is then attached to the tube *e* by means of caoutchouc while the water is running from *c*. The cotton must not however *entirely* exclude the admission of air.

By slightly varying the size of the pointed orifice and the tightness of the wool, the supply of water may be regulated at pleasure. It is as well therefore to keep a few of these easily made drop-tubes ready at hand.

PHARMACY, TOXICOLOGY, &c.

Note on the Processes Employed by Chemists to prove Poisoning by Phosphorus, by M. Filhol.[1]

The frequency with which phosphorus has been used as a poison within the last few years has for some time attracted the attention of physicians and chemists. There is no doubt that in the present day the use of phosphorus has superseded that of arsenic in criminal poisonings; and the proof of poisoning by phosphorus in some cases presents serious difficulties of a nature to embarrass the most experienced chemists.

Three sorts of cases may present themselves. The first are those in which the matters to be examined may still contain some traces of free phosphorus. In such the process of Mitscherlich, with some modifications, may enable experts to arrive at positive results.

The second cases are those in which the suspected matters no longer contain free phosphorus, but may yet have some phosphorous acid. To prove the presence of phosphorous acid in the suspected matters may also lead to the proof of poisoning by phosphorus; but this proof involves a most delicate research. It is not sufficient to establish the fact that the substances operated on possess a decided reducing power, in order to be able to affirm that phosphorous acid has been found. It is necessary to prove that the phenomena of reduction observed are really owing to the phosphorous acid, and not to the organic matters which accompany it. But the facility with which phosphorus is changed into phosphoric acid in the operations, joined to the difficulty experienced in separating it from the organic matters which are associated with it, frequently hinder the chemist from arriving at an affirmative conclusion.

The third cases are those in which the matters under examination contain neither free phosphorus nor phosphorous acid.

Most of the authors who have written on poisoning by phosphorus direct us in such cases to determine the exact amount of phosphoric acid in the suspected matters, and to compare this quantity with that yielded by substances of the same nature obtained from subjects not poisoned. A report by MM. Persoz, Opperman and Villemin is generally quoted as a model to follow. These gentlemen have laid down rules to be followed in all cases in which neither free phosphorus nor phosphorous acid can be found. The report is a very remarkable one, and it led, in the case on which these gentlemen were consulted, to the discovery of a crime which would probably have remained unpunished but for the ability of the experts.

We may, however, inquire whether researches of the same kind would lead to the certainty that poisoning had taken place, if they were not, as in this particular case, corroborated by certain facts, which by themselves constituted almost as strong proofs as those which were obtained by chemical analysis. In order that we may safely infer that a subject has been poisoned from finding more phosphorus (in the form of phosphoric acid) than would be found in the most phosphorised matters of the animal economy, it is necessary to demonstrate that the tissues of a man and the alimentary matters which may be found in his digestive apparatus, can in no case contain a larger amount of phosphorus than that found in the most phosphorised matters of the system. But as yet no investigations have been made to establish:

1. Within what limits the amount of phosphoric acid found in the tissues of the body may vary; we do not know whether age, health, or sickness, or even certain pathological alterations may not produce an abnormal abundance of phosphoric acid and phosphates.

2. It is necessary also that we should know with certainty whether the phosphate of lime in bone may not be dissolved in some culinary operations on meats, and so a substance be introduced into the system much richer in phosphorus than any of those which compose our tissues. If such should be the case it will not be sufficient merely to estimate the phosphoric acid, but it will be important to show that this acid was not found in form of phosphate of lime.

PROCEEDINGS OF SOCIETIES.

SOUTH KENSINGTON MUSEUM, 21 *March* 1860.

On the Adulteration of Food, by Ed. Lankester, *M.D., F.R.S.*

I have thought it would only be a proper termination to these lectures if I made some remarks upon the subject of the adulteration of food. I have already mentioned the fact that many of the necessaries of life are fraudulently adulterated, and it is to this subject that I wish to draw your attention this evening. The whole subject of adulteration would, however, be far too wide a field for me to take up, and I must consequently confine myself to a few of the most important articles of food, and some of the most common forms of adulteration; I will also, as far as possible, confine myself to those adulterations which I think persons in almost any station of life will be capable of detecting; and I shall point out the method of detecting those adulterations, in such a manner that I hope every one of my audience will find themselves competent to repeat the experiment.

There are a few important points of view from which the subject of adulteration of food may be regarded: the first is that the public on purchasing adulterated food has to pay an exorbitant price for the article; for they do not pay for the *real* substance (which might be worth the money), but for an *inferior* article which is not worth so much. Hence a large amount of income is taken out of the pockets of those who purchase. But there is another more important view than this, which is, that those who will thus pick our pockets will not hesitate to take our lives; for many of the substances which are added to food are really poisonous in their nature, and thereby destructive effects sometimes take place as the result of these adulterations. I will just point out a few of the instances which I recollect at the present moment in connexion with the poisonous effects of adulterated food. I recollect a short time since at a public dinner that the person who supplied the dinner placed upon the table some green blanc-mange. Now he had gone to the chemist and druggist for a substance with which to produce this green, to please the eye and tempt the appetite, and the chemist had given him arsenite of copper, also known as Scheele's or Schweinfurth green; this beautiful substance which is used to colour paper hangings, and which even in that case

may sometimes be a source of poisoning; and the consequence was that, as the result, five or six persons were poisoned, and two or three died. Now here we have a case in which fraud was not intended, but for all that it was really a fraud to induce a person by means of a beautiful colour, to take poisonous food. It is only a few weeks ago since we read in the *Times* newspaper of several children at Clifton having been poisoned by some very yellow-looking Bath buns. I do not know what is the object of colouring them yellow, but I suppose it is for the purpose of making them to appear to have a quantity of eggs in them. In this case, however, the yellow colour was not made with the yolk of eggs. The person who made them had gone to the chemist and druggist, and asked him for something to make his buns look yellow. The chemist had intended to have given him chromate of lead, or chrome yellow, as it is called. But it so happened that the druggist, as is frequently the case, made a mistake, and gave him sulphide of arsenic, or *orpiment*, and the consequence was that instead of a slightly poisonous substance, he obtained a very poisonous substance, and two or three boys nearly died. There was a more melancholy case than this occurred at Bradford, and here was another case in which the druggist made a fatal mistake. Here is some plaster of Paris,—or sulphate of lime,—which is used for adulterating sugar lozenges, and called "*daft*." This substance was applied for, but instead of giving plaster of Paris he gave *white arsenic*. When the lozenges were sold in the market-place at Bradford, the consequence was that fifteen persons were killed, besides many more being made seriously ill; so that you see the habit of adulteration leads to results which are frightful to contemplate. The man who wanted to put upon the table green blanc-mange, was simply wanting to tempt appetite by a particular colour. The man who wished to tempt appetite by colour in the buns, poisoned his customers, and the same in the case of the "daft." I shall have a word or two to say about the state of the legislature presently, which allows fraud of this nature to pass far too lightly. The man who picks your pocket, or steals your game, is sent to gaol,—the man who takes your life on the highway is hanged, but the adulterator who gives you slow poison goes scot free.

Now it is not alone that persons are thus poisoned and defrauded of their money, but the consequence of many of these adulterations is that people are not properly nourished, they do not get the right kind of food. If you give a child flour mixed with chalk or sulphate of lime, you are gradually undermining that child's constitution by depriving him of the phosphate of lime necessary for the formation of bone, and there are many cases in which, when bread has been permanently adulterated in this way, that persons, children especially, have lost their lives.

There is some difficulty in knowing what to call adulteration. The substitution of any one thing for another, with the intention to deceive, or with the intention to obtain more money than the thing is worth, is an adulteration. There are some things which are supposed to be improved by the addition of other substances, and these are commonly supposed not to be adulterations, and it would appear that in order to convict a person of adulteration there should be the intention of deceiving for gain. Now with regard to the more intimate nature of these adulterations. At first sight, when we glance our eyes around at the various kinds of adulteration, it would be difficult to classify them, but Dr. Hassall, who has written and done so much good in this respect, divides adulterations into three kinds: first, the addition of substances to increase the weight or bulk of food; second, the addition of substances to give the rich flavour or pungency of good food to inferior food; and thirdly, the addition of substances to give false or imitate natural colours. And I will just give you some instances of these different kinds. Taking those adulterations which are used for adding bulk and weight, we may divide them into two kinds, those in which addition is made of inferior or cheaper articles of the *same* kind, and those in which cheaper articles of *another* kind are added; for instance, I may say that when arrow-root is adulterated with inferior kinds of potato starch, it of course lowers the price to the seller, who however charges full price to the consumer, as though it were the real substance. Now potato starch is sometimes added to the arrow-root, and sometimes other starches. We find also that tea is adulterated with spent tea-leaves; this is the same kind of leaf, but it has lost its value and quality by use: these leaves are dried, made up, and added to the unused tea. We have, however, a large number of instances where the object is to increase the bulk and weight of the article by the addition of other substances. Thus, for instance, in bread we have mashed potatoes sometimes mixed with wheat flour, and although we might say that mashed potatoes contain starch as well as wheat, yet if we pay for good wheaten bread we have a right to have it. Then we find that butter is adulterated with lard, and that is a very difficult adulteration to detect. Coffee is adulterated with chicory, which is ground up and used instead of the coffee berry. Then milk is adulterated with water, which is a very different thing to milk. Pepper is adulterated with flour. Tobacco is adulterated with water and other leaves; and I might go over a great many substances which are adulterated for the purpose of increasing their bulk. Then we have another kind of adulteration; things are added fraudulently to articles to increase their pungency and flavour, and here water plays a very important part. For instance, vinegar is adulterated with sulphuric acid, by the addition of which the acidity is increased very much, and the adulterator is thus enabled to add a considerable quantity of water. Then beer is adulterated with salt and treacle. Now salt and treacle enable the person who adulterates to add water without destroying the power of forming a *head* when poured out. Powdered ginger has flour added, and then Cayenne pepper, for the purpose of making up the pungency. Then certain adulterations are used for the purpose of giving colour, for there is a great tendency in the public to prefer bright and intense colours; and we thus find that even such a thing as these anchovies could not come into the market without being mixed with Venetian red or peroxide of iron. Then coffee, in order to make it look of a darker colour, is adulterated with burnt sugar, *black jack* as it is called. Cocoa paste is adulterated with red lead; and as to confectionary, there is no end to the variety of injurious or poisonous colours used.

These, then, are the principal forms which adulterations assume, and the question comes what means can we employ to detect these adulterations? At first sight it seems a very difficult thing for the public to do, and the government is now engaged in passing through the Lower House a bill by one of the clauses of which analysts may be appointed in many districts, who for a certain price will have to analyse all kinds of food which may be brought to them. At the same time it is not so difficult a matter as at first sight it might be supposed to detect adulterations, and I will now draw your attention to some of the means which may be employed, namely, the microscope and chemical analysis. I will allude first to the microscope, which has become now so much an instrument of education that every person ought to possess one, and I have no hesitation in recommending its study not only to those who make scientific investigations, but also to every housewife: for you can imagine how much benefited a blind housekeeper would be if she could have a pair of eyes, but I venture to say that a housewife *with* eyes would be just as much benefited by the aid of a microscope as the blind housewife would be by the use of a pair of eyes. By the aid of a microscope we have a new world opened to us, and if any instrument could have been made purposely to arrest the progress of the adulterator more advantageously than another, I think it would be the microscope. As we shall have occasion to speak very frequently of the microscope, I will remark that although you may spend very advantageously your 50, 100 or 150 guineas (and I do not know, if you had the money, that you could spend it more advantageously than upon a good microscope),

those who have not the 150 guineas can purchase a very good small one for 30*s.* with which you can see hundreds of kinds of adulterations.

The other great detector is chemical analysis. That is not quite so easy, for it requires you to get up a little knowledge of chemistry — of the compounds of elements, of acids, bases and salts, and some of the general laws of composition and decomposition. But that is not so difficult if persons would only put their shoulders to the wheel. There are abundance of lectures and places of chemical instruction in London which they might attend, and a very little attention would enable a young person to muster enough of the subject to detect all sorts of adulteration. I do not say this so much for persons who have allowed their young days to pass without educating themselves in chemistry, but I say that it is the duty of these older persons not to allow the young to have the important study of chemistry systematically excluded from their education; for there is not one school in ten in which they are taught that there are more elements in matter beyond the four elements which the Greeks taught, air, earth, fire, and water. All this kind of knowledge ought to be taught in the present day, and I believe that there would be more classical and mathematical knowledge, if the boys were allowed a relief to their minds in the study of natural science.

I will now proceed to speak shortly of the subjects down on the list. First of the adulterations of the beverages— then respecting the heat-giving foods, starches and sugars, and oils; then the flesh-forming food, and lastly the condiments and spices. Speaking of beverages, I believe on the whole that the great manufacturers, the great producers of wine, beer, or spirits, are not in the habit of adulterating these things. The very extensive analyses by Dr. Hassall show that these substances do not, as a rule, contain anything which has been added for the purposes of adulteration. It is after they are handed to the person to sell by retail that they are adulterated, and probably the most extensively adulterated in this list are the various forms of beer, bitter ale, and stout, which are sold in the public houses. I have before alluded to the practice of adding a little salt, which gives it an increased specific gravity, without taking from its flavour, and enables the publican to add water; and I will just show you how you may detect salt in beer. If I take some salt and put it into a glass, and add water, I shall form a solution of salt, which is the chloride of sodium of the chemists; and the best way of detecting the presence of this salt, is by the addition of some nitrate of silver. Supposing you had beer to analyse, you would have to pass it first through animal charcoal, in order to get rid of the colouring matter, and then on adding a solution of nitrate of silver to the chloride of sodium, you have a precipitate of chloride of silver, a very beautiful thick, white, cloudy precipitate, which there is no mistaking. Now suppose treacle or sugar has been added, you must evaporate the beer to dryness, and then ascertain the quantity of sugar left,—that quantity is about the same in all good brewed ale, stout and porter; and you will find in this museum a quantity of analyses of these beverages, and then by comparison, you will soon see whether sugar has been added to any considerable extent. With regard to pale ales, they have obtained an unenviable notoriety in consequence of the report having got abroad some time ago, that they were adulterated with strychnine, a poison which has the power of producing a contraction of the muscular system, and persons who take a fraction of a grain of it die with frightful convulsions. It seems a frightful thing to think that this should be put into beer for the purpose of making it more palatable; and although it has been found that pure strychnine is not put in, yet the active principle of strychnia is contained in the beans called *nux vomica*, and these beans have been sold for centuries by persons who are not ashamed to call themselves brewers' druggists. The presence of strychnine is easily detected by taking a little piece of bichromate of potash and putting it upon a white plate. By then adding sulphuric acid to it, you produce a coloured liquid which when you add strychnine to it becomes of a very intense and characteristic violet. No other substance but strychnine produces the same colour. You see I have here a beautiful violet colour, which is spreading itself round on this plate, and when seen closely it is exceedingly characteristic of the presence of strychnine. I believe there is no other substance which when in combination with sulphuric acid and bichromate of potash, will produce this beautiful colour. Dr. Hofmann told me at the time when he was investigating the question whether the bitter beers of England contained strychnine, that he could detect the presence of the $\frac{1}{1000}$ part of a grain in a gallon of water. Now I would here remark that supposing the beer were adulterated with nux vomica, the poisonous substance would still be strychnine, and you would obtain the evidence of the strychnine from the nux vomica as from the strychnine itself. There are some other things which are said to be added to beer, but I will not detain you by going over them; salt and sugar are the things mostly used.

With regard to spirits, gin is adulterated with sulphuric acid and sugar, and this is very easily detected by nitrate of baryta, which gives rise to an insoluble white precipitate when it is added to a solution of sulphuric acid. Not only is gin adulterated with sulphuric acid, but vinegar is also adulterated with the same agent. It is added to gin because it tends to give the gin a greater amount of pungency, and in that state it admits of a large amount of dilution, for there is scarcely any of the gin which is sold retail at the public houses which does not contain a certain quantity of sulphuric acid and sugar, and the quantity of alcohol is reduced to very much below the amount contained in the gin as supplied by the distillers. I will say, however, with regard to those gins which the distillers call family gins, or cordial gins, that they consider themselves privileged to add a certain quantity of sugar.

Then, passing from gin, I might say a few words upon wines. We pay a high price for wines, but we cannot detect the adulteration by the means of reagents, as they undergo a more refined process of adulteration. There are chemists, in France more especially, who are able to imitate those *bouquets*, those scents, which no chemical reagents will detect: they are volatile, and will not remain for any length of time. We have heard something lately about publicans' port, which is so coarse and of so horrible a flavour. It is principally composed of cider, brandy and catechu. No persons who are in the habit of drinking port can possibly mistake this for the genuine article. In this case the tannic acid of the catechu may be detected, as also the malic acid of the cider.

Now let me come to the tea, of which there is so large a consumption in this country; and it is of much importance that we should get it pure. But, unfortunately, the English are not the only persons guilty of adulterating this article, for we have it sent from China in a state which is palpably adulterated. We have on the table a tea called by the Chinese Lie tea, and it is not inappropriately named, for there is not any tea in it at all. It is made of sweepings of various kinds, which are treated with prussian blue, and afterwards polished with lamp black, and thus it is made to assume the appearance of green tea. I brought this up from Liverpool, where there are several chests, consigned to this country upon speculation; but the Excise got information of the fact, and will not allow them to be cleared inwards from the dock. At one time there was a treaty going on for the purpose of sending them to America, but whether brother Jonathan has got them yet I do not know. Tea is sometimes adulterated with other leaves which are not poisonous, but they are not tea, and do not contain the active principle of the tea— the *theine* or *caffeine*, for it is the same in both. Now there is no substance which acts in the same way as theine. The only article which can come in competition is this Paraguay tea, which actually does contain the same substance. The Government has taken especial care that none of these things shall be sold as tea, forbidding, in fact, the sale of any kind

of leaf which can be used in the manner of tea. I have here a number of leaves of the tea plant, to show how the other leaves can be detected by comparison. Here is the leaf of the green, and here of the black, which is larger; and here the Assam tea, which is broader, and if you take the leaves, spread them out, and stick them down with gum arabic, you will see the differences between them. Here is the beech leaf, here the poplar leaf, the oak leaf, the willow leaf, and the sloe leaf, all of which have been actually added, and some dried and sold as tea, not as China tea, but for the purpose of making an article called British tea. These were seized, and their sale forbidden. I have here a number of other teas. Here is Swiss tea, prepared with a variety of Alpine plants, but none containing the theine. Here are the leaves of the pine; here the New Jersey, an American tea from a plant allied to the buckthorn. Here is the Lapland tea, and here is a tea which is most extensively used in Mauritius. Where the aromatic substances are used they are used for the sake of their essential oils. Sometimes we find teas adulterated with salts of iron, which give a green colour to the leaf, but the salts of iron are easily detected by putting to a solution a little prussiate of potash, which gives the substance known as prussian blue, at once an indication of the presence of iron. I do not know anything that is more decided, or any experiment more easily performed, than this for the purpose of detecting iron.

I now come to coffee. There is nothing which has been so extensively adulterated as coffee. Here I have a variety of things which are boiled and made into a beverage in the same way as coffee. None of these contain the same active principle as the tea—the theine, which is contained in the coffee leaf as well as in the tea. Here I have the lupin seed, beet-root, parsnips, dandelion-root, acorns, and so on; all are taken and made into their respective substitutes for coffee. They may be, any of them, mixed with coffee, and they thus become adulterations. But of all the substances chicory has been most extensively employed. It is not an uncommon plant in our country; it grows in abundance in the chalk districts. It has a little root which, when dried and roasted, is added to coffee by the French, and by various people on the continent of Europe, and they think it improves the flavour of the coffee. There is no doubt it does decrease the acridity of the coffee, but it is now fraudulently sold to the public as coffee. Now there is one way of finding out this adulteration very easily, not requiring the microscope, or much chemical knowledge. If you take a little coffee and drop it gently on some water, you will see that the coffee swims on the top of the water; but if you drop chicory in the same way you will see it sink rapidly through the water. Now I have here a mixture of chicory and coffee, and you will see that a certain quantity will remain at the top and other portions go to the bottom, so that by putting a little of this into a glass of water you will speedily have a correct idea of the quantity of chicory you have purchased. So by taking a small portion of the suspected coffee and putting it under the microscope you will be able to detect the chicory. The latter has ducts and cells, none of which are found in coffee, and when you see these ducts and cells you may be sure of the presence of chicory in your coffee. But chicory itself is adulterated with starch and other matters, and Dr. Hassall gives us a series of adulterations of chicory, many of which cannot be detected without the aid of the microscope and chemical analysis.]

Cocoa paste, which is prepared from the seeds of the *Theobroma cacao*, a plant which grows in America, sometimes contains red lead, which is put into the cocoa paste for the purpose of giving it a red colour. This is easily detected. If we put a little cocoa paste containing red lead into some water, and dissolve it by the agency of some acid, nitric acid for instance, and then add some iodide of potassium to it, we shall get a beautiful reaction. We immediately detect the salts of lead under whatever form we find them. I will take a clear solution of acetate of lead, and we shall there see the beautiful reaction of the iodide of potassium on this salt. Now I make no doubt you will see the beautiful yellow precipitate. In this way we may detect all the salts of lead. There are other tests which may be employed, but the iodide of potassium is the best. Now not only have we red lead, but starch of various kinds mixed up with the cocoa. The microscope, however, will detect them all.

Passing on from these beverages, I come to the various kinds of food. Here are the heat-giving foods, and I will just call attention to the inferior kinds of starches. Arrow-root, sago, and tapioca are starches. Arrow-root is expensive, sago and tapioca less expensive, consequently we frequently find that arrow-root is adulterated with sago and tapioca. The finest starch may be obtained from these substances, and it is not of very much importance detecting it; but if a person wants arrow-root, and is willing to pay for it, he ought not to have sago, tapioca and potato starch. Here is some from France, called *tous les mois*, of which the grains are very large. West Indian arrow-root is smaller in its grains, and East India arrow-root has smaller grains still, but they all have those peculiar markings on the surface by which it is easy to distinguish them from sago or tapioca. It is more difficult to detect the potato starch when this West Indian and East Indian arrow-root and all these things are mixed up with it. I know of no other means by which starch grains are detected than by the microscope and iodine. You will see, however, that there are other kinds of starch — wheat, barley, and oat; and by study you will soon find that each may be distinguished from the others: the starch of flour, for instance, having that peculiar kind of hexagonal grain.

Passing on from the various starches I come to the saccharine matters. Sugar is not subject to adulteration in the state of white refined sugar. The brown sugar may be moistened, and a very damp sugar is always to be suspected. Sometimes it is very carelessly mixed up with coarser kinds of sugar, and those sugars which have been carelessly kept for a long time are deteriorated. For instance, it is very common to find a little insect called the sugar mite, which is always an indication of the careless way in which the sugar has been kept, but is not evidence of fraudulent adulteration. Now I pass on to the various forms of prepared sugar which are known under the name of comfits, bon-bons, and so on, and sweetmeats of this kind are liable to extensive adulteration. I will just say with regard to white sugar comfits, that they contain flour, sulphate of lime, or daft; and with regard to flour, that which I stated would detect the presence of starch will detect the presence of flour, which contains starch; but with regard to daft, it requires some chemical ingenuity to detect it. Then with regard to these dangerous colours. I do not think that people can detect these things at all, they must apply to the chemist; but the best thing to do if you must give your children sugar, is to give them that from the table which is not adulterated. Take your common refined sugar of the table, which is much better than these coloured sweetmeats. I must say, however, that there are some manufacturers who never put in mineral colours. Here are green, blue, and red vegetable colouring substances, and these are comparatively inert; but, as a matter of precaution, it is better that persons should not take coloured sweetmeats at all. The green are sometimes coloured with arsenite of copper, which is a most deadly poison. If you wish to know whether a green sweetmeat is coloured with this arsenite of copper, you must dissolve it as far as possible in water, and then take the residue which is left and dry it, and then on exposing it to heat in a test tube, you will volatilise the arsenic, which will condense upon the glass, and by the aid of a microscope you will see the crystals. In the same way we detect the vermilion, which is a bisulphide of mercury and poisonous. But these are difficult processes, and can only be satisfactorily carried out by those having a competent knowledge of chemistry. I will, however, put you in the way to do them when you are at home. Now passing on from these more dangerous substances, I will just say that Venetian red and

armenian bole and other similar substances are all more or less objectionable, but not so objectionable as the mercury and the arsenite of copper.

Now I come to those substances which we call flesh-forming foods, and first of all milk. There is every reason to believe that milk is adulterated extensively with water. Here I have some milk from Mr. Hancock's in Brompton, in which you find we have a large quantity of cream; but this I have adulterated myself in these tubes with various proportions of water, showing you that as the quantity of water is increased, the proportion of cream is decreased, and in this way we judge of the extent to which milk has been adulterated with water. By a set of tubes like these you may compare your milk from day to day, with any known standard. There is also another way of judging of the purity of milk, by taking the specific gravity, which answers very well provided the milkman knows no other way of adulterating it except by water. Here I have an instrument marked with water and milk, and the markings between the two indicate different proportions of water and milk. Chalk is said to be sometimes added, but I should say that he is a very unskilful milkman who would add chalk. You can easily detect it by evaporating the milk, incinerating the residue, and then adding vinegar. The moment it comes in contact you will see an effervescence. If you use sulphuric acid instead of vinegar, the effervescence is more intense. Now sugar is sometimes added to milk, and it is said animal matter, sheeps and calves brains are mixed. Well, if you use your microscope skilfully, you will be able to detect those. Those who are going to impose upon the public should know that we can detect every possible adulteration.

I have now come to isinglass, which is adulterated with gelatine, and this is very difficult to detect. You pay 16*s.* per lb. for isinglass and 8*s.* per. lb. for gelatine, and if you pay for isinglass you ought to have it.

Then there are the anchovies with the stupid adulteration of Venetian red. The public will not buy them white, hence the importance of the public knowing what is the true colour of the anchovy and of the colour added to it. Then there are other things substituted for anchovies. I could tell you how to distinguish anchovies from sprats, herrings, or sardines, only one has not time; but by a little attention you can easily detect whether the anchovy is pure.

Ox-tongue has frequently horse's tongue substituted for it. Here is one, and here is a horse tongue cured in the same way; you may know the difference by the spoon-like expansion at the end of the horse's tongue as compared with the ox-tongue.

With respect to preserved meats, here is a thing which is of serious consequence. You have all seen the account of those poor men who have just returned from our Indian empire after fighting our battles, and have been starved on the way home. When recently at Liverpool, I was perfectly astounded at the amount of adulteration going on. On board the ships I saw that which had been shipped as coffee, and which was no coffee at all. Biscuits, utterly unfit to eat, going on board ships; and now we find these preserved meats, which are utterly unfit for food. There ought to be some superintendent to examine these things, so that large quantities of food like this would never pass; so that poor men after all the struggling, striving, and fierce contentions in fighting our battles, should not be starved coming home.

Now we come to the most important articles, bread and flour. We will take the adulteration of the bread with alum. This is not a necessary adulteration. If a baker is going to make bread with *bad* flour, then he supposes that he will make a better looking loaf by using alum, but he does it fraudulently. It is ridiculous for bakers to say that they cannot make bread without using alum, for it is well known that there are thousands and thousands of families in this metropolis who never use baker's bread at all, but good wholesome home-made bread and prefer it. You can sometimes smell which is the alum bread and which is the bread without alum; but that is not always to be done by bread on the table. By taking some aluminised bread and making a solution of it, and then treating the solution by adding hydrochlorate of ammonia and liquor ammonia you throw down a precipitate of alumina. But alum is not easily detected in small quantities, for there are other substances which may be thrown down; but wherever it exists there is no doubt that it is a bad thing. Alum combines with phosphoric acid, and forms a substance which will not dissolve in the stomach. Our bones are made of phosphate of lime, and if the alum deprives the stomach of the phosphoric acid by the introduction of this alum into the bread, and producing compounds which are not easily soluble, we deprive the bones of the nourishment necessary for their development. Bone dust or sulphate of lime mixed in bread will be detected by the microscope.

I must pass over the whole subject of condiments and spices; but there is one article, tobacco, on which I must say a few words. All true tobaccos are covered with little hairs, which can only be detected by the microscope. If you have tobacco cut up ever so small, you do not cut away those little knobbed hairs. Now the leaves used for tobacco have other kinds of hairs, and those are very important in the detection of adulteration and attempted frauds upon the revenue. I hope I have said enough of the importance of this subject. If I have drawn your attention to it it is sufficient; if I have enabled you to form something like an opinion of the value of legislation upon the subject. I have drawn your attention to the fact that a bill is before Parliament for the purpose of appointing a public analyst, to whom you will be able to apply if you suspect an adulteration of your food; but this bill does not go far enough. We should imitate our French neighbours, who seize on the adulterated goods, put the adulterator into prison, and shut up his shop for the term of his imprisonment; and, so long as the man is in prison, his shop has a label upon it stating that it is shut up for adulteration, and that the proprietor is in prison.

I have now to thank you for your attendance in this course, and to announce to you that as you have so kindly attended here on these occasions I am induced to go further, and have undertaken to deliver a course of lectures on the *Animal Product Collection*, and those commence on Tuesday, the 10th of April, to be continued on the five succeeding Tuesdays. The first subject will probably be *Silk and its Dyes*; the next *Wool and Hair*; then *Leather*; the *Manufacture of Leather out of Skins*; the *Manufacture of Glue and Gelatine*; and then will probably follow *Bone and Ivory*, and some remarks on the *Utilisation of Waste*.

SOCIETY OF ARTS, 21 *March* 1860.

W. B. Carpenter, *Esq. M.D., F.R.S. in the Chair.*

On this occasion, Dr. Guy of King's College read a paper on *A New Method of Obtaining Crusts of Arsenic, Arsenious Acid, and other Sublimates*, introducing also various microscopic contrivances to the notice of the Society. Although the paper was certainly a useful one in many points of view, it dealt too much in trivialities to carry any great weight with it, and we cannot help saying that we expected better things from Dr. Guy, who shall now introduce himself.

"As the simple chemical manipulations of which I am about to speak have for their aim to prepare a new class of objects for examination by the lens and microscope, and as the other suggestions to which I have alluded have either grown out of the use of a disc of glass, instead of the usual microscopic slide, or imply the substitution of the one for the other, I will begin by saying a few words about these discs of glass.

"For some years past I have been in the habit of using these discs, and of late especially, on account of their convenience for comparative chemical experiments on the small scale. They are almost necessary for sublimates obtained by heat, and very useful when we wish to obtain a number

of crystalline deposits from solutions at the same time. A great many of these discs can be put under one bell glass, and protected from the intrusive London dust.

"It is a very small matter to speak of, but I may state here, that for these minute chemical operations I find a little instrument, consisting of a spear-shaped piece of common window-glass, mounted in a wooden handle, more convenient than the common glass rod. It acts as a spatula, a coarse filter, and a good drop at the same time. You can put a small quantity of a salt on a piece of window-glass, rub it down with the flat side of this glass spatula, suck up the clear solution by the capillary attraction of the two surfaces of glass, and then drop a large or small drop from the point. I send round a specimen of this very simple chemical tool. I may add that in using the common solutions for these small experiments, I always employ a drop bottle of the form which I now send round. It is a hollow tube drawn to a point, and ground as a stopper into the neck of a bottle; a small hole at the top of this tube converts it into a pipette.

"To the other and more important use of the glass disc, (I mean for obtaining sublimates by heat), I shall allude presently, after I have spoken of the size of the disc, of the mode of adapting it to the microscope, of similar discs made of other materials, and of the art developments to which the use of it has led."

A minute description of the disc itself follows, but our readers may briefly learn that it is about an inch in diameter, or rather less, and cemented in the centre of a piece of wood of the size of an ordinary microscopic slide, having an aperture rather smaller than the glass. Some cells for mounting in fluid were then noticed, those of Messrs. Powells' manufacture being apparently the best, as, although blown, tolerably flat surfaces were retained. Returning to the glass discs, Dr. Guy proceeds:—

"I have said that these discs are serviceable for obtaining chemical sublimates, such as those of metallic arsenic and white arsenic, by heat. I think it quite possible that the habit of using these discs proved suggestive of the very simple modification of the common reduction tube of which I am now to speak.

"For obtaining crystals of arsenious acid, or crusts of arsenic in medico-legal inquiries, the chemist uses a glass tube, of small bore, about three inches long, open at one end and sealed at the other, The tube has the proportions of the test tube I hold in my hand, but the bore is much smaller. This tube should be of German glass. It should be carefully dried before it is used, and the white arsenic, or the mixture of this with charcoal, or of the sulphuret of arsenic with black flux, or the metallic arsenic itself (the result of some previous chemical operation) must be introduced into the tube without soiling its sides. Then, having passed the middle portion of the tube through the flame of the spirit lamp, the flame is applied steadily to the sealed end. The white arsenic in sparkling eight-sided crystals, or the crust of the metal, collects on the sides of the tube about an inch or so above the sealed end.

"This operation is a delicate one, and many minute precautions must be observed in order that it may be satisfactorily performed; and, when the crystals or crusts have been obtained, they are certainly not in a favourable condition for further examination and identification. When, for instance, the crystals of white arsenic are small, they are not readily identified by lens or microscope upon a rounded surface with a sharp curve, and streaked with lines in the length of the tube.

"The number of precautions to be observed, and of fallacies to be guarded against in this mode of procedure, led me to adopt the modification which I am about to describe. In the place of a small reduction tube of green glass, three inches long, I use a larger specimen tube, about three-quarters of an inch long, of common white glass. Into this short tube, from which the moisture is readily driven off, I introduce the white arsenic, the metal, or the mixture. I place the tube in a vertical position, and support it there by letting it fall into a circular hole punched in a sheet of copper, or drilled in a slab of porcelain. This holder may be supported either on a frame attached to the spirit lamp (in which case it should be made to turn over the flame or from it) or on a common retort holder, the spirit lamp being removed at will. The specimen thus adjusted and fixed is then heated to expel the moisture it contains, and the substance to be operated on is dropped into it from the point of a penknife. A disc of common window glass, thin, white, and free from defects or scratches, is then dried and heated in the flame of the lamp, and placed upon the mouth of the tube. On heating its contents, the crystals or crusts are deposited partly on the sides of the tube, and partly, but chiefly, on the flat disc of glass. The coating of the glass disc may then be examined by the lens or microscope, and may be treated, in every respect, as an ordinary microscopic object."

Omitting a few unimportant observations, we find the following more definite statement:—

"I will illustrate the delicacy of this method which I have been describing by an extract from a paper on the subject, published in Dr. Beale's *Archives of Medicine*, No. iii. 1858.

"Four small slips of microscopic glass, each bearing a minute fragment of a crust of arsenic, were weighed in an assay balance, and found to weigh respectively 0·280, 0·230, 0·137, and 0·141 of a grain. The slips having been carefully heated in a small specimen tube three-quarters of an inch long, suspended in a metal holder, yielded distinct circular mists, and lost respectively 0·003, 0·003, 0·001, and 0·001 of a grain; so that two of the crusts weighed each the three hundred and thirtieth part of a grain, and each of the two remaining crusts the thousandth of a grain. Examined by the lens all the mists were found to consist of brilliant detached points, distributed evenly over the surface, which under the microscope could be readily identified as octahedra. Both the mists yielded by the thousandth of a grain could be easily resolved into octahedra, under an eighth power of the microscope, and one of the two, by the successive removals just described, was found to consist of crystals, which could not be less numerous than 250,000,000 to a grain of metallic arsenic, a number which I believe to be greatly under-estimated. Successive experiments with minute quantities of metal, apparently not exceeding the thousandth of a grain in weight, all yielded the same decisive result: so that I feel justified in stating that by this simple method a crust of less than the thousandth of a grain of metallic arsenic may be identified with ease and certainty.

"I shall perhaps commend this plan to the Society if I state that one of the very earliest results accruing from the use of it, was the discovery that metallic arsenic when deposited from its vapour, on cooled surfaces, presents itself in the form of globules. This fact is partly of importance as giving extension and precision to our knowledge of the properties of a most important poisonous substance, and partly as connecting arsenic with other elements with which it was already known to have analogies, I mean sulphur, mercury, and selenium, which, like arsenic, are deposited in a globular form. There are specimens of all these substances under the microscope as well as of some other sublimates obtained in this manner. I need scarcely add that this method gives great facilities for examining the crystals of arsenious acid, which, though usually described (and correctly) as right octahedra, sometimes assume the shape of right prisms, and occasionally, though only rarely (as I have ascertained), the form of the cube."

There remain yet two "new adaptations" to consider, which Dr. Guy respectively designates a "class microscope," and an "illuminated cell." The first consists merely of an ordinary Coddington lens, inserted in a brass eye-piece, screwing into a ring of the same metal, which latter is fixed into a convenient handle; a ledge at the other side of the ring receives the glass disc with the arsenical sublimate, or other microscopical preparation on its surface, and a brass

screw-cap renders the whole secure. As the lens screws easily in or out, its force can be adjusted without trouble. In some varieties of the instrument the cap is furnished with an oblong slot, so that objects can be examined mounted either upon a disc, or on a slide of the usual dimensions. The "illuminated cell" is for opaque objects only, and is made by pressing a circular piece of tinsel having a central perforator into a concave form, thus producing in fact a small Lieberkühn for each object, an arrangement which seemed to answer very well. The doctor concluded his paper by directing attention to the various instruments and specimens exhibited. Among the former we noticed a contrivance intended to be used either as a microscope or telescope, for the capabilities of which Mr. Matthews of Lincoln's Inn is responsible. Dr. Guy's "class lens" is manufactured by Mr. Baker of Holborn.

The Chairman, in pointing out the advantages accruing from Dr. Guy's method of obtaining sublimates, said that with the old reduction tube, where the deposit was necessarily of a cylindrical form, nothing more powerful than a hand lens could be employed for examining it, whereas upon the flat surface of a glass disc, a high power could readily be applied. While upon the subject, he would name another application of the microscope to the detection of minute quantities of chemical substances, viz. that of Dr. Richardson, who had ascertained the presence of ammonia in the breath of animals by its means. The plan adopted by him was to cause the breath to pass along a small trumpet-shaped tube, having a bulb near its larger extremity, containing hydrochloric acid. Consequently the ammonia in the breath was converted into chloride of ammonium, and deposited in excessively small crystals upon a slip of glass placed across the mouth of the tube. He only mentioned this fact to show the value of the application of the microscope where very minute quantities of substances were concerned. He personally did not find the glass discs so handy as the ordinary slides, but saw many advantages in Dr. Guy's system. The flat surface bottles would, he thought, be most useful in museums. With regard to the "illuminated cell," he might mention that some specimens prepared in a somewhat similar manner by Lieberkühn himself, were in the museum of the College of Surgeons. The adaptation of a piece of tinsel was a great simplification.

Dr. Letheby had great pleasure in stating that Dr. Guy's method of recognising arsenic was employed in his own laboratory, and he felt thankful for its introduction. He traced the progress of toxicological research from the trial of Donald in 1815 up to the present time. A little while before that, as described by Hahnemann, 10 grains of arsenic were required to make the metallic test satisfactory in a court of law. Afterwards Dr. Black improved the process, and could detect the poison if he had *one* grain to operate upon. It was thought a marvel of toxicological skill when Dr. Chistison said he only required the 16th of a grain, but that evening they were told how to trace the presence of the 250,000,000th of a grain of arsenic! He also enlarged upon the uses of the microscope in detecting the organic poisons by the identification of their crystals, and considered that the process of Dr. Guy would greatly elucidate that branch of the subject.

Mr. Wentworth Scott said that it was of great importance that the surface for receiving arsenical deposits should not only be flat, but should also possess a tint suitable for showing microscopic crystals well by reflected and transmitted light. He submitted for inspection a specimen of the slides he had had specially prepared for this and other purposes, which were coated on one side with a film of "opal glass," both surfaces being highly polished. They answered so well that he never employed porcelain. A metallic deposit was admirably shown by reflected light upon these glasses, while crystals of arsenious acid were best seen by sending the light through the opal, all inconveniences arising from the great refractive power of many objects being avoided by its use. He wished to say a word against the ordinary form of Marsh's apparatus as supplied by philosophical instrument makers, which he considered unfit for any important researches, the bulbs, generally, not more than an inch and a quarter in diameter, being far too small. He preferred to use a small Wolffe's bottle, fitted with a bulb-tube. He thought that one phenomenon which he had observed in using this process had not been noticed in any work on the subject, and that was, when the suspected animal matter, more especially liver, perhaps, had not been completely oxidised, a deposit much resembling arsenic (or antimony) was often obtained, consisting really of carbon, or some peculiar carbonous matter with a metallic lustre, and requiring a microscope to detect it. He had known many analysts deceived by this, and although, of course, no one should be content with a single test, he thought that the point should be brought forward more prominently in our schools of science than it was. He employed sulphuric acid and bichromate of potassa for oxidising with entire success. He could corroborate the Chairman's remarks upon the presence of ammonia in the breath, having had the honour of being intimately associated with Dr. Richardson in his experiments, and had detected very minute quantities, the ·008 of a grain, and even less, of ammonia in the breath and blood of animals.

In compliance with the Chairman's request, Dr. Letheby explained his modification of Marsh's process, in which the great delicacy of the latter is combined with the certainty and facility of Reinsch's method. He first slightly acidulates the suspected liquid with nitric acid, raises it nearly to the boiling point, and then introduces some pieces of zinc. If arsenic is present the zinc becomes coated with it in a few minutes, when it may be removed, washed, and used in the ordinary way for the generation of arseniuretted hydrogen. Both Marsh's and Reinsch's tests were open to one great objection, namely, that they failed to show the *quantity* of poison found.

Dr. Thudichum made a speech of some length, the chief object of which appeared to be to throw cold water upon the sublimation tube and discs of Dr. Guy, and to show that the microscope was quite useless in analytical researches. He described in detail all the usual methods for separating arsenic, including those of Wöhler, Fresenius, Rose, Bloxam, &c. but which we will not repeat here for fear of wearying our readers. He would use (Dr. Thudichum said) the very example adduced by the Chairman in favour of the microscope, as a proof of its fallacy. Crystals had no doubt sometimes been obtained from the breath by method before named, but whether they consisted of chloride of ammonium, or of the many hundred substituted ammonias, or even contained any ammonium at all, there was no evidence to show, the appearance of crystals of all the Amine bases being nearly alike. He considered that Dr. Guy's method would offer no advantages to the medico-legal chemist.

Mr. Wentworth Scott referred Dr. Thudichum to Dr. Richardson's essay on the blood, wherein it was stated that the presence of no particular ammonia had been determined; all that was stated being that the solubility of the fibrine during life was due to an exceedingly minute quantity of *an* ammonia of some kind. Every chemist was aware of the immense number of ammonias that existed, chiefly eliminated by the splendid researches of Hofmann, aud that the crystals of their chlorides greatly resembled each other, but none could mistake the chlorine compound of an ammonia for the chloride of anything else. He believed that a special ammonia existed in the blood of each distinct animal or class of animals, and trusted that the point might ere long be determined. He differed with Dr. Thudichum in relation to the microscope, which he considered no chemist could dispense with. As regards the processes named for the detection of arsenic by the last speaker, he thought them too complicated where only small quantities could be expected, and would mention in conclusion, that if the organic matter to be examined were dried at a very low temperature and then treated with pure benzole the fatty matter could be extracted, and the oxidation tendered comparatively easy.

After a few remarks from Dr. Guy, who also differed entirely from Dr. Thudichum, the Chairman proposed a vote of thanks to the author of the paper, which having been passed, the meeting then adjourned.

The Society of Arts' Annual Exhibition of Recent Inventions will be opened upon the 9th of April. A series of Notices of the Exhibition, from the pen of a member of the society, will *shortly appear* in the Chemical News.

NOTICES OF PATENTS.

Improvements in the Manufacture of Steel and Wrought Iron, by W. H. Nevill.

Every one is aware of Bessemer's method of decarbonising cast iron, by forcing air through it at the fusing point. In this case the temperature rises immensely owing to the heat produced by the combustion of the carbon and part of the iron. Mr. Nevill instead of forcing air through the melted metal, causes the latter to fall from a height upon a cone; in this way the exposure to the air is obtained upon which he relies to remove the excess of carbon. He paves the floor with cast iron plates, and in the centre places a cone 18 inches diameter and 9 inches high. It is mounted on a standard which raises it to 3 feet 6 inches above the floor. The exit for the metal is so arranged that it falls directly on the cone, which scatters it, and allows it to fall on the floor in a purified state. The spot on which it falls is enclosed, so as to retain it in its place.

The plan is simple, ingenious, and does not appear to contain any obvious sources of error. How is the mass broken up for working into shape or subsequent fusing?

Method of obtaining Potash and other Products from Suint, by Edmé Jules Maumené *and* Victor Rogelet.

"Suint" is the greasy matter found in the skin and hair of sheep. The patentees find it to be the potash salt of some organic acid or mixture of acids. The chief peculiarity of it is the fact that the potash is almost absolutely free from other metallic oxides. The suint is washed with cold water which does not touch the grease, but only dissolves the "suintate of potash." The latter when evaporated has the appearance of baked molasses. It is calcined in close vessels and yields the usual products of the distinctive distillation of nitrogenised organic matters, namely, tar, ammoniacal water and gases. The carbonate of potash mixed with charcoal is then lixiviated, and the solution evaporated to dryness. Any sulphide formed in the first evaporation (owing to the decomposition of sulphates by the free carbon) may be removed by calcining in a reverberatory furnace or stirring the solution with a little white lead.

The wool washed by the patentee's process is much whiter than when scoured in the usual manner.

"One thousand pounds of raw wool, of whatever country, yield generally from one hundred and forty to one hundred and eighty pounds of dry suintate (or salts) of potash, soluble in water. This "suintate" produces nearly fifty per cent. of carbonate of potash, that is to say, from seventy to ninety pounds, including the chloride and sulphate, which together, barely amounts to five or six pounds."

The patentees claim all the products formed. The carbon remaining after calcination is said to be suitable for pigments. They carefully prepare the ammoniacal salts and tar for sale, as also the chlorides and sulphates, which they separate by crystallisation from the solution of the crude carbonate of potash. They also collect the fatty substances of the wool. Owing to the extreme purity of the potash producible by their process, they claim every substance made from it, even saltpetre and potassium. This appears to us to be a most valuable patent. Every claimant is aware that the potash of commerce (and its salts) are liable to contamination with soda and other impurities. Now there are numerous operations, especially in scientific chemistry, where the absence of soda is of importance, and this process, as opening up a method of supplying a want greatly felt, is especially valuable. Moreover, in wool countries the quantity of suint will be sufficient to enable considerable sums of money to be annually obtained from an otherwise useless product. We think, however, that there was no great necessity for claiming the preparation of nitre and potassium from the suint potashes.

CORRESPONDENCE.

Dr. Guy's Lecture on Arsenious Acid.

To the Editor of the Chemical News.

Sir,—From a notice on the cover of the present number, I perceive that in next week's Chemical News you intend to print the paper read at the Society of Arts, on Wednesday evening last, March 21, by Dr. Guy, *On a New Method of obtaining Arsenical and other Sublimates, for Microscopic Examination.* In doing so, I trust you will intimate to our provincial and continental brethren, that you do not publish it as a fair specimen of the practical chemistry of the London laboratories.

All that Dr. Guy proposes to do is done in a far better way by simply fixing a small round piece of glass, such as a microscopic covering glass, on to the end of a glass rod, or into a holder improvised out of a piece of platinum wire, and passing it as far as necessary down a common test-tube, at the bottom of which is the substance containing the volatile matter. Heat being applied, any portion of the sublimate that escapes condensation on the little piece of glass will probably condense on the upper and cooler part of the test-tube, and not be altogether lost, as must inevitably be the case in Dr. Guy's arrangement.—I am, &c.

Tyro.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

Artificial Production of Minerals.—M. Debray[1] has recently succeeded in preparing artificially several crystallised phosphates and arseniates identical in form and composition with the natural mineral. When an insoluble carbonate is digested with an excess of phosphoric or arsenic acid, the carbonate is generally changed into a crystallised phosphate or arseniate. The water of hydration varies according to the temperature. At the ordinary temperature carbonate of lime and phosphoric acid give a phosphate of the composition $2CaOHOPO_5 + 4HO$. At 212° the compound $2CaOHOPO_5$ is obtained. At the same temperatures exactly corresponding compounds are formed with arsenic acid and carbonate of lime. The compound $2CaORsO_54HO$ is found native and is known under the name of Baïdingerite.

When the acid liquid in which the carbonate has been digested is decanted and heated, other equally well crystallised compounds are obtained. The solution of arseniate o lime heated to 158° gives $2CaOAsO_53HO$: heated to 212 it yields the compound $2CaOAsO_5HO$. Phosphates of zinc copper, and manganese, and arseniate of copper can be pro cured in the same way.

Insoluble phosphates and carbonates of lime, magnesia, &c act on a metallic nitrate and sulphate, and produce crystallised compounds, whose composition varies according to the temperature at which they are formed. At a little over 212° Debray obtained the phosphate $4CuOPO_5HO$ (libethenite), and the arseniate $4CuOAsO_5HO$ (olivenite).

Crystallised double phosphates are formed when acid

[1] *Comptes-Rendus.*

solutions of phosphates are mixed with metallic solutions. Acid phosphate of copper and nitrate of uranium gave the double phosphate of copper and uranium, chalcolete.

II. ORGANIC CHEMISTRY.

A New Mode of Substitution, and the Formation of Iodobenzoic, Iodotoluylic, and Iodoanisic Acids, by M. P. Griess.—M. Griess[2] has before announced the existence of a new class of azotised acids, formed by the acid of nitrous acid on the amid acids of the benzoic group. By treating amidobenzoic acid with nitrous gas he obtained an acid $C_{28}H_{11}N_3O_8 + 3HO$. He now describes the action of acids upon this new body. On treating it with strong hydrochloric acid it becomes hot and nitrogen is disengaged. The addition of water to the evaporated liquid separates reddish flocculi, which by crystallisation from alcohol furnish chlorobenzoic acid. By continuing the evaporation the hydrochlorate of the amido-acid is obtained:

$$C_{28}H_{11}N_3O_8 + H_2Cl_2 = \underbrace{C_{14}H_7NO_4.HCl}_{\text{Hydrochlorate of benzamic acid.}} + \underbrace{C_{14}(H_5Cl)O_4}_{\text{Chlorobenzoic acid.}} + N_2.$$

Idobenzoic Acid, $C_{14}(H_5I)O_4$, is formed on treating the nitro-acid with hydriodic acid. It is very slightly soluble in water, but dissolves freely in alcohol and ether. It crystallises in long scales. In contact with fuming nitric acid it is changed into nitroiodobenzoic acid. Its silver salt forms an amorphous white precipitate.

Idotoluylic Acid, $C_{16}(H_7I)O_4$. This acid is formed with the nitro-derivative of the toluic series, as iodobenzoic acid is in the former case. It crystallises in nacreous scales, is slightly soluble in water, and freely soluble in alcohol and ether.

Iodoanisic Acid, $C_{16}(H_7I)O_6$. Its mode of formation is the same as the preceding. It crystallises in fine white needles, insoluble in water, but very soluble in alcohol and ether.

Glycolic Ethers.—M. Lourenço[3] shows that these ethers may be easily obtained by heating in a sealed tube to about 200° C. equivalent proportions of the acid and glycol. In this way he has made (as Mr. Simpson had before) the *mono-acetic glycol* obtained in other ways by Mr. Atkinson.

Monobutyric Glycol is a colourless oily liquid, insoluble in water, soluble in alcohol and ether, having an odour like butyric acid. It boils at 220°.

Monovaleric Glycol is also a colourless oily liquid, insoluble in water, and soluble in alcohol and ether. It smells like valeric acid. The boiling point is about 240°.

Diacetic and *divaleric* glycols are formed by heating glycol with an excess of the acids. The latter boils about 250° C.

Mixed Ethers may be formed by treating as above an ether of glycol with one acid radical by another acid. M. Lourenço has obtained acetobutyric and acetovaleric glycol in this way. The latter is an oily, colourless, neutral liquid, soluble in alcohol and in ether, and boiling about 230°.

Action of Organic Chlorides on Glycol.—M. Lourenço[4] also notices that the chlorides of acetyle and butyryle act with great energy on glycol at the ordinary temperatures. If, however, they be mixed in a cooled tube, it may be sealed before the action begins. Chloride of acetyle and glycol heated in a tube for some hours gave water and the *acetohydrochloric glycol* of Mr. Simpson.

III. CHEMICAL ANALYSIS.

Detection of Peroxide of Lead in Litharge.—Stein[5] heats the litharge in a test tube with chloride of sodium and bisulphate of potash, and introduces into the tube a slip of paper coloured with a solution of indigo. If any peroxide be present chlorine is disengaged and bleaches the paper.

Platinising Glass and Porcelain.—Every one who has experimented with an extemporised Marsh's apparatus has found that after the gas has burned a short time the glass tube has become fused and the aperture closed. Herr Dullo[6] says this may be prevented by platinising the extremity of the tube. He draws out the tube, files it to make it a little rough, and then dips it into a strongish solution of bichloride of platinum, so as to take up a drop or so. He then carefully heats the point until it acquires a beautiful metallic lustre. By repeating this four or five times a good coating of platinum is obtained both outside and inside.

In the same way the author platinises porcelain crucibles, using of course unglazed ones for the purpose.

IV. TECHNICAL CHEMISTRY.

Manufacture of Beet-root Sugar.—Various methods have been proposed for removing the lime dissolved in the syrup when that agent has been used in the purification of the juice. Carbonic, pectic, oxalic, phosphoric, and tannic acids, and soap have been proposed at different times; and now M. R. Wagner[7] recommends oleic acid. When this is agitated with saccharate of lime, the latter is quickly removed; but unfortunately as the oleic acid is generally contaminated with some volatile acids (capric and caproic) the sugar acquires a rancid taste which is very difficult to remove. Melted stearic acid will answer the same purpose; and the soap formed being decomposed by a strong acid, the stearic acid can be recovered and used again.

The author also proposes to use gelatinous silica.

SCIENTIFIC NOTES AND QUERIES.

Electrical Decomposition of Compounds of Nitrogen.—Sir,—Professor Faraday, at p. 217 of his *Lectures on the Non-Metallic Elements*, remarks, as one of the peculiarities of nitrogen, that "electricity determines no liberation of nitrogen from any of its compounds." Mr. Grove, at p. 93 of his *Lectures on the Correlation of Physical Forces*, asserts that "ammonia, protoxide of nitrogen, deutoxide of nitrogen, &c. are decomposed by the action of the discharge." I shall feel thankful by being informed which of these contradictory statements is correct.—*E. G.*

Apparatus for keeping a Liquid at a constant Level.—Sir,—Will Mr. *John Tillman* be so kind as to inform a student of chemistry in what the apparatus devised by him for keeping up a constant level in a fluid differs from Gay-Lussac's washing apparatus, described in every work on chemistry which touches on manipulation.—*B. X.*

ANSWERS TO CORRESPONDENTS.

*** In publishing letters from our correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

Excelsior.—1. An alloy of 8 parts bismuth, 5 of lead, and 3 of tin, fuses a little below 212°. 2. There is no rule that we know of. 3. See p. 194.

A Constant Reader.—The course of study extends over five years; three of which must be spent in attending hospitals and classes. The candidates are examined in anatomy and physiology and surgery.

W. P. (Oldham)—1. The effects of the alkaloids could not be at all controlled by the mixture you mentioned. 2. To make caustic soda take 2 parts of quicklime and 10 parts of common soda, and water according to the strength of the solution required. 3. It can only be procured direct from America. We do not know the price.

G. B. (Nottingham)—The best account at present is to be found in Gmelin's *Chemistry*, vol. xi. We shall have papers on the subject soon.

J. C.—It would be impossible to say without experimenting.

E. J.—Sulphide of calcium made into a paste with water is the most harmless preparation to use. It must be washed off in a quarter of an hour.

B. B.—Received.

J. J.—Declined with thanks.

*** All *Editorial Communications* are to be addressed to Mr. Crookes, and *Advertisements* and *Business* communications to the Publisher, at the Office, 12 and 13 Red Lion Court, Fleet Street, London. E. C.

Vol. I. No. 18. — April 7, 1860.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Notes on Boiling-Points, by ARTHUR H. CHURCH, *F.C.S.*

ONE great difficulty besets all attempts at drawing correct conclusions concerning the boiling-points of homologues, isomers, metamers, &c., the determination of boiling-points being of necessity referred to an arbitrary barometric pressure. The alteration in boiling-point, consequent upon an alteration of pressure, is by no means the same for all liquids. Then, too, the determination is often made somewhat carelessly: perhaps the pressure is not noted at all, or the thermometer is incorrect, or the presence of moisture is not guarded against; or maybe the substance itself is not pure; finally, oxidation of the substance may occur from the action of the atmospheric air in the heated vessel. From time to time, however, some very interesting relations between the boiling-points of various organic substances have been pointed out, chiefly by Kopp. One thing is certain, that under a pressure of 760 mm. the elevation in boiling-point for an increment of ΘH_2 is not the same for all homologous series, and it seems probable that it is not of equal value in different parts of the same series.

It is remarkable that the substitution of 1 eq. of methyle for the 1 eq. of basic hydrogen in the series of acids of which formic acid is the first member, *reduces* the boiling-point by about 63° C. for this substitution is really the addition of ΘH_2. If for the basic hydrogen of formic acid we substitute ethyle, the boiling-point is lowered 44°·7, or 63°—18°·3. A similar relation may be observed between water (*hydric acid*, or hydrate of hydrogen) and its ethyle derivatives, alcohol and ether:

	Boiling-point.	Difference.
Water, H, HΘ	100°·0	
		21°·5
Alcohol, Θ_2H_5, HΘ	78°·5	
		21°·5 × 2
Ether, Θ_2H_5, $\Theta_2H_5\Theta$	35°·5	

Here the substitution of Θ_2H_5 for H in water (really the addition of $2\Theta H_2$), reduces the boiling-point 21°·5, while the substitution of a second eq. of H. by a second eq. of Θ_2H_5, which is the introduction of another $2\Theta H_2$, lowers the boiling-point by twice that amount. Also, where 1 eq. of H in hydrate of ethyle is replaced by methyle, the boiling-point is lowered about 63°. Replacement of the H of HCl, and of NH_3, types of other classes of chemical compounds by organic groups, instead of reducing the boiling-point raises it.

On careful collation of all the boiling-points of organic substances which have been accurately determined, it seems that a difference in composition of ΘH_2, however caused, is indicated in homologues by a difference of boiling-point which seldom or never exceeds 27, and is scarcely ever less than 9 degrees centigrade. Whatever the reason, the actual numbers for the various series exhibit considerable fluctuations, as the following instances show:—

	Difference.
Nitrites of methyl and its homologues	26°·5
Oxides „ „	24·5
Radicals „ „	23·0 and 20°
Hydrates „ „	23·0 and 14°
Cyanides „ „	21·3 and 21°
Nitrates „ „	21·0
Formiates „ „	20·4
Acetates „ „	19·0
Butyrates „ „	17·5
Valerates „ „	17·0
Oxalates „ „	12·0
Acids of the formic series	20°·0; 19°·0; 18·5
Anhydrides „	12·5
Benzole series	22·3

But it is perhaps among the boiling-points of compounds containing nitrogen, and especially among the organic bases, that we find the most singular relations. On comparing the cyanides of ethyle, butyle and amyle, we find that the difference in boiling-point for ΘH_2 is as much as 21°:—

		Boiling-point.	Difference.
Cyanides of	Ethyle	82°	21°·3 × 3
	Amyle	146°	
	Butyle	125°	21°·0
	Amyle	146°	

And in the series of bases of which pyridine is the first term nearly the same values for ΘH_2 are obtained.

	Boiling-point.	Difference.
Pyridine	115°	
		18°
Picoline	133°	
		22°
Lutidine	155°	
		23°
Collidine	178°	
		20°
Parvoline	198°	

The mean here is about 20°7. But in the aniline series, which is isomeric with that of pyridine, the highest value assignable to ΘH_2 is 16°, and if reliance may be placed upon the boiling-points given as those of the higher terms of the series, the increment as we ascend is reduced as low as 12°. As aniline and its homologues constitute the starting-point of numerous other homologous series, such as those of methyl-aniline, methyl-toluidine, &c. we may expect that the boiling-points of the various members of these series, if accurately determined, will afford us some light as to the influence on the boiling-point of the various forms in which the increment ΘH_2 has been introduced. On comparing the methyle and ethyle derivatives of aniline and toluidine, and also of piperidine, a tolerably regular increment of 11° for each addition of ΘH_2 is observable:—

	Boiling-point.	Difference.
Aniline	182°	
		11°
Methylaniline	193°	
		11°
Ethylaniline	204°	
		11°
Propylaniline	215°	
Toluidine	198°	
		10°
Methyltoluidine	208°	
		10°·5
Ethyltoluidine	218°·5	

	Boiling-point.	Difference.
Piperidine	106°	11°
Methylpiperidine	117°	11°
Ethylpiperidine	128°	

In the case of ethylamine, diethylamine and triethylamine, the higher difference of 19° is caused by each increment of ΘH_2.

	Boiling-point.	Difference.
Ethylamine	19°	38° = 19° × 2
Diethylamine	57°	38° = 19° × 2
Triethylamine	95°	

The accuracy of several of the determinations given above is but doubtful: if, for instance, 95° be the correct boiling-point of triethylamine, it seems improbable that the boiling-point 91°, assigned to trimethylamine, or the number 95° for amylamine, can be true. Again, the cyanide of ethyle is said to boil but 5° higher than the cyanide of methyle, while the difference in boiling-point in all the other well-known terms of the same series is 21°. For further deductions, especially as to the influence of Θ and H on the boiling-point, we must wait till we have obtained more accurate and more abundant data. As yet there is scarcely anything to add to the speculations and calculations of Kopp, Gerhardt and Schröder on this subject.

On Osmious Acid and the position of Osmium in the list of Elements, by J. W. Mallet, *Professor of Chemistry University of Alabama.*[1]

Of the five oxides of osmium stated to exist, the second and fourth have not been isolated, although compounds containing them are known. While preparing osmium from some black platinum residues, the author obtained a substance which there is some reason to believe may be osmious acid, OsO_3, mixed indeed with osmic acid, but still permitting certain of its properties to be observed.

The residues were fused in an iron crucible with three times their weight of nitre. The fused cake, while still warm, was broken up and placed in a flask fitted with a long tube bent at right angles, and a funnel tube, the extremity of which was drawn to a small bore, and reached to the bottom of the flask. The bent tube was well cooled, and strong oil of vitriol was cautiously added, a few drops at a time, through the funnel. The acid produced intense heat on coming in contact with the cake of potash salt, and oily drops of a bright yellow colour soon began to appear in the cooled tube. These slowly congealed to a solid resembling unbleached beeswax. In time a considerable quantity of this yellow substance collected in the tubes and receiver. By gentle heating the whole was collected in the receiver and united under water to a single mass. Towards the end of the distillation *colourless* needles and fused drops of the well-known osmic acid came over, and doubtless a considerable proportion of the yellow mass in the recciver consisted of the same. Thinking the yellow colour was due to some impurity, the author cautiously resublimed the product, but it collected of the same tint as before. It appeared more fusible and volatile than osmic acid. The water in which it was fused acquired a bright yellow colour and gave off fumes, the odour of which seemed somewhat different from that of osmic acid, but which irritated the eyes so insufferably that it was scarcely possible to finish the work and put it up for preservation. It was, however, removed in a single cake, and sealed up in a perfectly clean glass tube. The water in which it had been fused, gave with caustic potash a very dark brown-red colour; such a tint as would probably result from a mixture of the red *osmite* of potash, discovered by Frémy, with the orange-brown *osmiate*.

The sealed tube containing the cake of yellow acid was exposed to the direct rays of the sun, when the acid immediately began to sublime upon the sides of the tube, not in long needles and prismatic crystals, like osmic acid, but in feathery crusts like sal-ammoniac, which under the lens had the appearance of minute octahedrons grouped together. The colour was still bright yellow; but in a short time it began to turn black, and in 24 hours the whole inner surface of the tube was black and opaque. Pure osmic acid exposed in the same way for weeks did not change. It is easy to imagine the cause of the change if the yellow acid be the teroxide mixed with osmic acid. The teroxide probably broke up into osmic acid and one of the lower oxides, or perhaps osmium itself.

In order to ascertain, if possible, what change had taken place, the tube was opened after three months. The black and partially friable contents readily sublimed, and condensed in yellowish needles, leaving a little black powder behind. The inner surface of the tube was coated with a thin crust of a black colour and considerable lustre, which experiments seemed to show was the protoxide.

What the yellow substance really was it requires further investigation to show. The author quotes Thompson, who observes that osmic acid sometimes has a tint of yellow; and Berzelius, who remarked that when sulphurous acid was added to a solution of osmic acid, the latter passed through various shades of colour, *yellow*, orange-yellow, brown, &c. which he attributed to the successive formation of sulphates of the binoxide, sesquioxide, &c.; but the author asks, may not the first step in the reduction have been osmious acid, giving the yellow colour?

The properties of osmium and its compounds are very remarkable, and render it a matter of no little interest to trace the analogies of this rare substance, and fix its place among the other elements. Reviewing the positions assigned to osmium by former writers, the author agrees with Dana, who places osmium in the "arsenic section," including nitrogen, phosphorus, arsenic, antimony, bismuth, and tellurium. The last named is doubtful, and ought rather, perhaps, to be placed with sulphur and selenium.

In a memoir published by Dumas on the numerical relations subsisting among the atomic weights of the elements, the arsenic series is thus given:

	Atomic weights.
Nitrogen	14
Phosphorus	14 + 17 = 31
Arsenic	14 + 17 + 44 = 75
Antimony	14 + 17 + 88 = 119
Bismuth	14 + 17 + 176 = 207

If osmium and ruthenium be introduced into the group, the latter must stand between phosphorus and arsenic, which osmium will follow:

	Atomic weights.
Ruthenium	14 + 17 + 22 = 53
Arsenic	14 + 17 + 44 = 75
Osmium	14 + 17 + 66 = 97

Besides these numerical relations, there is a clear resemblance running through the formulæ and properties of the oxides of these metals. On comparing ruthenium and osmium with the recognised members of the arsenic group, we find that both metals form protoxides, which

[1] Abridged from *American Journal of Science and Arts.*

are feeble bases, as are probably the corresponding compounds of the other members of the group. We next meet with sesquioxides, whose formulæ are exceptional in the series; but for neither metal has this grade of oxidation been obtained in the free state and pure, and in the case of osmium its existence may be gravely doubted. The binoxide of osmium is a feeble base, as is the binoxide of ruthenium. The teroxide of osmium is the body supposed to have been isolated in the experiment described at the beginning of this paper. Its position as a feeble acid, capable, however, under certain circumstances, of playing the part of a base, its fusibility and volatility (greater, apparently, than those of osmic acid, as nitrous acid is more fusible and volatile than hyponitric), its probable crystallisation in octahedrons of the regular system, in which arsenious acid and teroxide of antimony are also found, all tend to indicate homology with the other teroxides of the arsenic group. Just as we find hyponitric acid (NO_4) and antimonious acid (SbO_4) to be the most stable of the higher oxides of nitrogen and antimony, so the well known osmic acid (OsO_4) seems to be the grade of oxidation which osmium most readily assumes when not in contact with bases.

The tendency throughout the arsenic group is manifestly to the production of the acid compounds MO_3 and MO_5, the former the more fusible and volatile body, the latter the stronger acid. In addition we have some cases of the protoxide (MO) a feeble base, and the binoxide (MO_2) a body of still more feebly basic properties, verging upon the acids. All other grades of oxidation, as far as they exist at all, may perhaps be correctly viewed as compounds of the preceding *inter se*. The stability of the oxide (MO_4) in a separate state is remarkable—its formula is one of rare occurrence.

The affinity of all the elements of the group for oxygen is remarkable; it is so in the case of osmium, which, like arsenic and antimony, is clearly able to take up oxygen at common temperatures. Roasting at a red heat in a current of air, affords, as is known, a good method of obtaining osmic acid from platinum residues, just as by a similar process arsenious acid is prepared from native arseniurets.

It would be a matter of much interest to compare osmium with its supposed homologues, under circumstances in which we should expect it to play an electronegative part. Frémy has announced his belief in the existence of an *osmiuretted* hydrogen, but such a compound has not been isolated and described. Compounds of the metal with ethyl, methyl, &c. would be well worth examination, and it is not unlikely that such might be prepared.

The specific heat of osmium, as far as its value as a physical character goes, *opposes* the introduction of this element into the arsenic group. It has been determined by Regnault =·03063; multiplying by the equivalent 97, we have the product 2·9711, thus placing osmium in the list of elements (including the majority) for which the product of sp. wt. by at. wt. is nearly 3, while for phosphorus, arsenic, antimony, and bismuth the product thus obtained is twice as great, or about 6. In this respect, however, osmium probably resembles nitrogen.

Osmium is placed by Faraday, with some doubt, in the paramagnetic class; the metal and its protoxide were found to act feebly in this sense, while pure osmic acid is said to have shown itself clearly *diamagnetic*. The strongly diamagnetic character of phosphorus, antimony, and bismuth would render a re-examination of this point interesting.

Reviewing the united physical and chemical characters of osmium, and comparing them with those of the generally recognised members of the arsenic group, the author thinks he is justified in concluding that it is with them this metal should be classed in a natural arrangement of the elements.

TECHNICAL CHEMISTRY.

The Specific Gravity of Mixtures of Alcohol and Water.[1]

After three series of determinations which have occupied him more than a year, H. von Baumhauer has arrived at the conviction that the specific gravities of mixtures of alcohol and water as determined by Gilpin, Löwitz and Gay-Lussac are very incorrect. In the first series of experiments the mixtures were made by volume, but as these gave results so different from those generally received, the author repeated his experiments with mixtures made by weight as well as by measure. These, however, only confirmed the results previously obtained. The author started with absolute alcohol having a sp. gr. of 0·7946 at 59° F. In the second series alcohol from another source was used which had the sp. gr. 0·7947 at the same temperature. The water used in the experiments was distilled and carefully deprived of air. After corrections for slight mistakes the results obtained were as follows:—

Alcohol in 100 of the mixture.	1st series.	2nd series.
100	0·7939	0·7940
95	0·8119	0·8121
90	0·8283	0·8283

PHARMACY, TOXICOLOGY, &c.

On the Detection and Estimation of Phosphorus and Phosphorous Acid in cases of Poisoning, by Prof. Scheerer.[2]

In several communications on poisoning by phosphorus, Professor Scheerer confirms the extraordinarily poisonous nature of that body. In the case of a woman to whom the composition from 30 or 40 lucifer matches was administered in milk, death ensued within 48 hours. The amount of phosphorus in that quantity of the paste can hardly have exceeded 0·5 of a grain.

In every case brought under the author's notice, it seemed desirable to look for the presence of unoxidised

[1] *Comptes-Rendus*, t. l. p. 591.
[2] *Annalen der Chemie und Pharmacie*, Bd. cxii. s. 214.

phosphorus. For this purpose the process indicated by Mitscherlich was adopted with the modification that all the air was expelled from the apparatus and replaced with carbonic acid gas.

This was effected in a very simple way, by dropping a small piece of chalk into the mixture of sulphuric acid and the suspected matters (contents of the stomach, food coffee, &c.), and making the tube of the retort to dip into distilled water in the receiver.

In this way luminous vapours are not obtained in the distillation tube, as is the case when carbonic acid is not used; but instead of this the greater part of the phosphorus in the mixture is distilled unchanged (only a small part being transformed into phosphorous acid) both of which are condensed in the water contained in the receiver. This water becomes strongly luminous when gently agitated in a dark room, and contains the phosphorus in numerous little globules which may be melted into one by gently heating in a water bath.

If it be necessary to make a quantitative estimation of the phosphorus, it may be changed into phosphoric acid by means of an excess of pure chlorine, and then estimated by the well known methods. When the amount of phosphorus in the unoxidised condition is too small to to be obtained in globules, the distillate still shows luminous vapours in the dark. It also gives with nitrate of silver the characteristic blackish precipitate of phosphide of silver, or reduced silver, which equally establishes the existence of phosphorus.

The author also gives the following simple process for detecting the presence of phosphorus. Supposing the contents of a stomach, food, coffee, &c. have to be examined, they are placed in a flask mixed with enough distilled water to make a thin magma. Some pure sulphuric acid is now added, and a strip of paper slightly moistened with a weak alkaline solution of nitro-prusside of sodium is inserted, and held by a loosely fitting cork. If the least trace of sulphuretted hydrogen is developed the paper will be turned blue. Lead paper would in the same way be turned black. When convinced of the absence of sulphuretted hydrogen, hang in a piece of Swedish filtering paper having on it some lines and dots made with a solution of nitrate of silver, which will show the presence of phosphorus by becoming blackened from the formation of phosphide of silver. If the blackening takes place quickly, and is very intense when the flask is gently warmed on a water or sand bath, more paper may be suspended well impregnated with the silver solution. In this way a good quantity of phosphide of silver will be obtained. The paper may then be treated with chlorine water or aqua regia, the solution filtered from the chloride of silver, and the filtrate evaporated on a water bath. The formation of the ammonio-phosphate of magnesia or the yellow phospho-molybdate of ammonia with the residue is a certain proof of the existence of phosphorus in the matters examined.

When the object is to estimate quantitatively the still unoxidised phosphorus, the distillation apparatus of Mitscherlich is connected with a couple of two-necked bottles. The first of these must contain about an inch deep of distilled water, into which the tube of the apparatus must dip. The second must contain some neutral or slightly ammoniacal solution of nitrate of silver to fix all the phosphorus vapour which may not be condensed by the cold distilled water. After the distillation is finished the apparatus is disconnected, and the tube rinsed out with a little distilled water. The small globules of phosphorus in the first bottle may then be united by heating gently; and the water which may contain phosphorus vapour and a trace of phosphorous acid should be added to the contents of the second bottle. By gently heating the mixture phosphide of silver is formed. Some aqua regia is now added, and the whole is evaporated. On filtering from the chloride of silver, a clear solution of phosphoric acid is obtained, the amount of which may be estimated in the ordinary way, and the phosphorus calculated therefrom.

When the phosphorus has been changed into phosphorous acid the determination can be made in the same way. The suspected matters must be treated in the apparatus of Mitscherlich with some sulphuric acid and pure zinc as long as the hydrogen developed carries along with it any phosphuretted hydrogen, and the gases must be passed into a solution of nitrate of silver to fix the phosphorus. The estimation can then be made as before.

ROYAL INSTITUTION OF GREAT BRITAIN.

Friday, 23 March 1860.

On Diamonds, by Nevil Story Maskelyne, *Esq., M.A., Keeper of the Mineral Department, British Museum.*

Lord Wensleydale *in the Chair.*

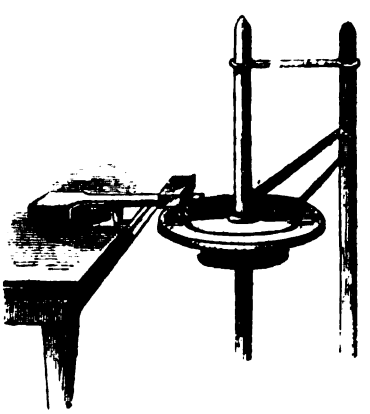
The progress of chemistry within the last few years has been rapid and very great, but rapid and great as that progress has been, it is principally to one branch of chemistry that it has been confined. For it has dealt more with synthetical processes,—processes which have to do with compounds and the classification of compounds, than with what might seem *primâ facie* to be the most interesting subject for chemical inquiry, namely, the nature and properties of the elementary bodies of which those compounds are made up. Thus this science is going on constantly and untiringly adding to its lists of compounds, and the now enormous volume of organic chemistry is no other than the chemistry of carbon. Yet if you ask the chemist what he knows about this carbon itself, it is surprising how little he has to give for answer. He knows, for instance, that in a variety of localities in nature is found a substance with by no means constant characters, called by the mineralogist graphite. He also knows that the body called coke is a product of the gas works. He knows that these and that charcoal and lampblack are carbon, and that the diamond is no less carbon. He further recognises in this wonderful body, called by the jeweller *carbonate*, a form of carbon possessing indeed more than the toughness with equal hardness, though with rare traces only of the crystal form and crystalline cleavable structure of the diamond; so that it is more like diamond than either of the other forms of carbon which I have mentioned. Beyond, then, the recognition of these apparently different shapes of carbon, the chemist can give little positive knowledge regarding the true nature of this protean and plastic element, for if you press the inquiry further, and ask him what he knows of the number of allotropic states in which carbon may exist, or the methods of forming these, he has to confess that he has but little sure knowledge on the subject. The crystalline form even of graphite is still not determined with certainty, and the formation of the diamond is an unsolved problem. Of all the forms in which elemental matter presents itself to us, there is not one probably in all the range of chemistry so interesting as that which I have selected for the subject of this evening. And what invests the diamond with this great interest? It is that the diamond is a substance which transcends all others in certain properties to which it is indebted for its usefulness in the arts and its beauty as an ornament. Thus, on the one hand, it is the hardest substance found in nature or fashioned by art. Its reflecting power and refractive energy, on the other

hand, exceed those of all other colourless bodies, while it yields to none in the perfection of its pellucidity. Indeed when one thinks of this hardest, most pellucid, and profoundly refringent substance as an elemental form of matter occurring in nature and thus highly endowed, one is tempted for a moment to see in it something of a realisation of that old idea of the philosophers of the days of Paracelsus, which believed it to be possible to extract from a given series of things a certain material essence endowed with the qualities of these things in an exalted degree and as it were in an abstract form, and which they denominated the *quinta essentia*.

First among the properties of this interesting mineral, the diamond, I will speak of that for which it is in its application the most useful and prominent—its hardness. There is no other substance yet known in nature rivalling it in this respect. Indeed, were the diamond not so beautiful a gem, its price in the crude state would hardly be less than it is now, for the uses to which it may be applied are innumerable, and its application to them is only limited by its rarity and cost.

First, I will invite your attention to its most ordinary application, namely, to the cutting of glass. It was shown by Wollaston that a fragment of diamond cleaved from a crystal in its ordinary condition, namely, with plane surfaces, will not effect an incision in the glass, but only abrades the surface of it, so that to cut the glass you must take those rounded crystals of diamond whose cusped edges are formed by the meeting of rounded facets, constituted apparently by an oscillation in the direction of the crystal forces, which may at one time have tended to deposit the molecules in planes parallel to an octahedron, at the next moment in those of a trihedral or hexahedral pyramid on each octahedral face. It is only these rounded forms that the glazier can employ. The *writing* diamond, on the other hand, is a mere fragment or splinter with plane sides. The rounded edge of the glazier's diamond forms a fine clean cut, while the other produces only a scratch. I will show you that presently by the aid of the electric light, by converting it to the purposes of a magic lantern. Another illustration of the uses to which the characteristic hardness of the diamond has been applied, is the cutting of the diamond itself. The diamond and other hard minerals are cut with the powder of diamond, and powder of diamond will alone cut the diamond. The process is performed by this apparatus, called a skyf (pronounced skiv),

Fig. 1.



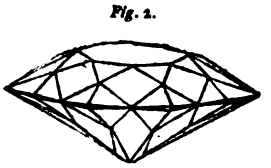
which consists of a plate of a peculiar kind of iron, neither too hard nor too soft, and which is made to revolve with an immense velocity. Upon this a very minute quantity of diamond dust, with oil taken from this small iron mortar by a quill, is carefully applied, and this soon becomes imbedded firmly in the iron, like the sand on sandpaper. This instrument is a brass hemisphere mounted in a stem, and it carries a mass of fusible metal into which, while yet very hot and soft, the diamond is inserted. The hole is here where the diamond was placed when the last stone was cut; then this arm, carrying the diamond in its metal setting, is placed upon the table with its end projecting over the skyf, and with the hemisphere inverted, so as to bring the diamond into contact with the surface of the revolving plate. A weight is put upon this arm, over the end where the diamond is, and by a motion of the wheel in this direction the grains of diamond are brought to do their work. It is a beautiful thing to see the diamond cutter perform his operations, which he does with exquisite skill and almost mathematical accuracy. The first preparation of the diamond, indeed, is effected by actually bruising off the salient solid angles of the stones by a skilful grating of one against the other in this little box, a diamond being fixed to each of these little handles by cement, and the dust formed being caught in the box beneath, in which it is sifted. This diamond dust is, to the eye, of a peculiar grey colour, and Petzholdt says it never has the colourlessness of the diamond, but presents a grey hue from the pounded diamond being partly resolved into black particles. When, however, this dust is examined under the microscope (and I have examined it myself) it is perfectly pellucid and entirely colourless, for the grey hue is seen to be produced to the eye in consequence of the light being broken up by the highly refringent substance and strongly reflecting surface of the powdered mineral.

Well, now I pass on from these physical and practical illustrations of the hardness of the substance of the diamond to another subject—that of its optical characteristics. First of all, let me allude to its adamantine lustre, arising from the completeness with which it reflects or throws off from its surfaces so large a portion of light, I do not say every ray that falls on it, because part of that light enters the diamond and undergoes refraction in it. There is a little lost by the sort of scattering produced by the mechanical imperfections of the polish, but in the diamond this is extremely little, and almost the whole comes off to the eye or is transmitted into the body of the diamond. When you pursue this question further and ask what becomes of that ray of light which enters the diamond, you find that the retardation of its velocity and consequent divergence from its course is in the diamond exceptionally great. In fact, though there are two or three transparent substances known which are more highly refringent than the diamond, they are minerals of deep red or yellow tint, while of colourless minerals generally, and especially those stones coloured or otherwise whose lustre and beauty have made them gems, none approaches the diamond in refringent energy. To give you an idea of the intensity of this refractive power, I might say that the refractive index of glass is to that of diamond somewhat as the ratio of the figures 16 to 25, so much more is the diamond refractive than glass. To explain this more exactly, suppose a ray of light passing through the air or any other substance impinges upon the surface of some denser medium, say water, or glass, or diamond, then if its course be at all inclined to the surface of that medium it is diverted from the direction of that course, and is plunged more or less profoundly downwards into the denser substance. You will, I think, understand this at once by looking at this card model. You will find that the sine—as this horizontal moveable bar, always perpendicular to the vertical line, is called—I say this *sine* of the incident ray is always greater than the sine of the refracted ray. How much greater? Its magnitude is measured by this law: that in every substance there is a given figure by which you must multiply *this* sine, the "sine of refraction," to produce the incident sine. Whatever the position of this ray, then the sine *here* will bear to the sine *there* exactly the same proportion. Now supposing this, the incident, ray becomes horizontal, *i. e.* to say parallel to the surface of the refracting medium, then the progress of that ray is arrested at a certain angular distance from the vertical line, and this angle is called the critical angle. Now let us

suppose the ray to be travelling in the opposite direction, *i. e.* from the denser to the rarer medium, so long as its direction is along a line comprised within that angle, there is a possible direction in which it can emerge. That emergence will take place then at an angle corresponding in its sine to the requisite multiple of the sine of the angle its course makes in the denser medium; but when it exceeds that critical angle in its original direction where is it to go to? how is it to emerge? there is no possible sine now for any angle at which it *can* emerge. What will become of such a ray? Experiment answers this question. The ray incident on the rarer medium beyond the critical angle is totally reflected into the denser medium again. Here is an experiment or two that will exhibit this. [But first I will fulfil my promise to exhibit to you the results of the use of the cutting and the writing diamond. You see there I throw upon the screen three or four marks on the glass. That one to my left is the clear cut of the cusp-shaped edge of the glazier's diamond; then that diagonal mark is a *crack* in the glass; and then there are two *scratches* from the writing diamond. One can thus very clearly see the different results in the two cases.]

Now to illustrate what has been said of total reflection. I have here a little prism which is constructed at such an angle that if a ray enters it on this face, thus, it comes in contact with the second surface of the prism at so high an angle that it is impossible to pass out through that surface though transparent, and the result is that I have total refraction; but, first of all, I must explain to you that when I throw the image thus totally reflected on to the screen, it will exhibit the result of any other image seen by reflection, namely, it will be inverted so that the points of glowing charcoal, which are now seen directly on the screen, will be seen topsy-turvy when thrown there by a total reflection. Now I shall be able to direct that totally reflected image to the screen, and I hope thus to show you that the rays are in this way completely reflected from the second surface of this prism. Now I will bring into that beam my prism, and you see immediately I get an inversion of it. You see I pass it up and down, and there it is traversing the screen inverted; that then is a proof of the total reflection of the light at the second surface. Let us try another way of illustrating this. Observe, I make the same image now travel along the ceiling, down this side of the room, and so right under where I am standing, and up on the other side. Now if that prism would allow any light to go through it (and remember it is a simple piece of polished glass), you would see it on that screen, but there is darkness, so that all the light must have been reflected. I have dwelt on this so long that I might be able to illustrate to you the subject of the Brilliant. The jewellers prefer the diamond when it is cut in what is called the brilliant form, that is to say, in the form depicted here (*fig* 2), which is a rough sketch only of a not very perfect form of the brilliant, that into which the Koh-i-Noor now is shaped.

Fig. 2.



The prism, which is formed by one of these lozenges on the so-called bezil, and by those two opposite "pavilion" facettes, must be so formed as not to allow any light to pass through it. For this purpose it must be so constructed that the angle here at the girdle must be twice the limiting angle which I have explained to you. Now, in consequence of the high refractive power of the diamond, and the resulting smallness of the critical angle, we are able to construct a prism of diamond with an angle of 46° that will as effectively cause all light to be totally reflected at its second surface, as one of glass would do with the far larger angle of 80°, or one of sapphire with an angle of 68°, and the consequence is that you are able with the diamond to get a brilliant of flatter form than with any other substance. Thus by giving a proper inclination to the planes that form the bezil on those that form the pavilion of the brilliant, and by properly proportioning the extent of the *table* facet and the little facet, called the *collet* or *culet*, which truncates the portion of the stone below the girdle, we obtain the remarkable result that no light can escape through the diamond downwards, except the few rays that traverse it perpendicularly on the culet. All the other rays will be reflected totally from the pavilion facettes and from the culet, and will have to emerge again, at various inclinations, from the summit planes; and as they will emerge at such inclinations, they will necessarily be broken into the prismatic colours. The precise adjustment of the angles, and the dimensions of the planes of the brilliant, is a mathematical question which has hitherto perhaps never been fully investigated.

I am indebted to Mr. Martin for the magnificent display of brilliants and other diamonds, including this most beautiful series of naturally coloured diamonds, which I am able to show you to night. Indeed, if some small principality is looking out for a sovereign, I would recommend Mr. Martin to them, as being able to take his regalia with him. I will now pass an intense beam of electric light into this splendid brilliant of nearly 20 carats. See, its image on the screen forms a black opaque square, so that the diamond actually acts as a screen, and not a trace of light comes through it except that small quantity which passes in perpendicularly through the table, and out at the culet. No experiment can be more satisfactory than that to prove how completely the diamond cutter has attained his object, and that remember by an art — like so many other arts — ripened long before science had explained its instinctive principles, for at the time of the first cutting of brilliants the law of refraction even could hardly have been known.

Now, when I am about it, let me exhibit this diamond to you, under conditions at once novel and dazzlingly beautiful. See it now glowing in the intense light of this electric luminous beam. Look at it — please to observe not only the reflected splendours, but the wonderful intrinsic luminosity of that diamond. It glows like the sun. Look about the room and on the ceiling, at the dazzling lights reflected from it. But there is an intensity about its own brilliancy which is not alone due to the light which is being thus powerfully poured into it and is as fiercely fighting to get out again, but is due also to a power the diamond has of absorbing and appropriating, so to say, and giving out that light again, a power of fluorescence. I may add that in making some experiments yesterday, with Dr. Faraday and Dr. Tyndal, we came across another phenomenon with another diamond belonging to Mr. Martin. After we had kept that diamond for some time in this electric ray, and then extinguished the ray, the diamond retained a phosphorescent light of its own for at least three quarters of a minute afterwards. I will now illustrate by experiment, the dispersion into the prismatic colours, of the light which falls at inclined incidence on the faces of the brilliant as it emerges from it. The diamond though so very powerfully refringent in its action on light, is not relatively nearly so dispersive; that is to say does not refract the differently coloured rays with so varied an energy as many other substances do. The spectrum thrown by the diamond is, however, wonderfully intense and distinct and beautiful, more so really than that from glass. It would be hardly fair indeed to compare this large and brilliant spectrum thrown from this fine flint glass prism with any that I could form by means of this small brilliant; because, as compared with the glass prism, the diamond is but a mere fragment (although valued at hundreds of pounds). It is a thin "spread" brilliant, which I found in the collection of Mr. Martin, having its facettes so cut as to comprise the angle I require. Here then is the spectrum from the diamond thrown upon the screen. As I said before, you will reason not by direct comparison of the size or

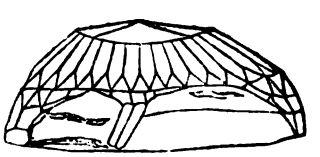
intensity of the two spectra formed by it and by the glass, but by comparing the results with the prisms that produce them. This little fragment of diamond is throwing a spectrum quite comparable, in the clear separation and purity of the colours, to that proceeding from the glass prism.

Let me now advert to another subject, namely, the geographical and geological association, and the chemical history of the diamond. I shall say but little about it. India, Malacca, Borneo, Brazil, Mexico, the United States, the Ural Mountains, and, as has been asserted, Australia, and also (though it needs much to be confirmed) Algiers, these are all localities in which the diamond is found, and in them all it occurs in alluvial soils, which are the result of the attrition and wearing down of older rocks. The theories dealing with the formation of the diamond are many. We have the authority of Liebig in support of the view that diamond has been produced by a process of eremacausis, such as has gradually resulted in the formation of anthracite. Another view supposes it to be possible to separate carbon in the diamond state from chloride, sulphide, or iodide, or from some other binary compound of it, by the intervention of some third element which shall have power gradually to replace the carbon. Then another has been suggested that, although we have never seen carbon at a temperature sufficiently intense to convert it into vapour, and though we have no proof that it was ever in a state of vapour, yet it would seem reasonable to suppose that, under proper conditions, carbon ought to vaporise, and might then condense as diamond—that is a third theory. And a fourth might be that, supposing the diamond to be incapable of undergoing fusion at ordinary pressures (though there seems no reason to suppose it is not), yet, on the further supposition that—as in the case of arsenic, the fusion of which does not take place under the atmospheric pressure, from the immediate conversion of the solid into the gaseous element—so (as may be effected with arsenic) by the combined influences of intense heat and great pressure, molten carbon *might* be formed, and the cooling of this might produce diamond. M. Desprez, indeed, has laboured hard to produce the diamond from the passage of a Voltaic current, for long periods of time, one of the poles being of carbon; but these labours have, I fear, not been rewarded with the success which the patience they represent would seem to deserve. But there is, besides all these speculations, another direction in which the production of the diamond may be looked for. It is well known that iron, when surcharged with carbon, though it may dissolve it when in a state of fusion, deposits the excess of carbon as it cools, but deposits it in the graphitic modification. Some other metal, or some change in the conditions with the same metal, might cause the extrusion of the carbon in the form of diamond. Another theory again may be founded on the analogy of the silicates from which magnesium, when burnt in contact with them, separates the silicon, as does lithium at a temperature far below red heat. Some alkaline or earthy metal, it might be reasoned, may, under special conditions, set free the carbon from carbonates, by an analogous reaction. Chemistry is certainly not in a position to deny such a possibility.

But on reviewing all the facts that are known regarding the parentage of the diamond or its rock home, wherever that may be, it must be confessed that we are in the dark. Its origin in the earth, indeed, and the manner of making it in the laboratory are two distinct questions; but in our real ignorance of both, we may discuss them as if they were one. The companion minerals associated with the diamond in alluvial soils are, like it, wanderers from more or less distant mountains, which mountains have been produced by earthquake forces, or have been acted on or changed by terrestial heat. They are, in fact, composed of metamorphic rocks, whose age is unknown, and whose characters are probably due to the transmuting agency of chemical forces, powerless for effecting change in any ordinary period of time, but acting slowly and surely, and producing complete transformations of mountain strata, such as that from clays to slates and schists, when their operation has been aided by comparatively low degrees of heat, and been extended through periods that make the thought giddy. What then are the companion minerals thus occurring with the diamond? Universally gold is its more or less near neighbour. Platinum is rarer but hardly less ubiquitous. Then in addition to oxides of iron and of titanium, we have tourmaline, topaz, chrysolite, chrysoberyl, kyanite, and other gems; in fact a large assortment of minerals, in which silicates were the chief ingredients. And that is not all, for itacolumite, a rock of which this flexible sandstone is a kind, occurs in several of the diamond countries. It is a rock composed of quartz grains, in layers, cemented by mica, often too by talc, and associated with other minerals. This specimen is from India, that from Brazil, close to the diamond country, and in this rock in Brazil the diamond has actually been found. Nor is that all: last year it has been shown that the diamond occurs in hornblende slate in the Brazilian province of Minas Geraes. Let me also add one fact, which may prove a significant one. In two or three important diamond districts dolomite also occurs. But to the chemist all these facts speak in a vague language, for they do not tell him whether the diamond has been formed in the primeval clay or other deposit from which these metamorphic rocks may have originated, or has been produced during or even since the metamorphic transformation of them was effected. Nor do the substances imprisoned in the diamond throw much light on this inquiry. Splinters of ferruginous quartz are certainly so enclosed, and gold has been said to be so in a diamond now at Vienna. But besides these nothing but carbon has been proved to exist in the flaws of the diamond. But the chemist has at least one great result of his own laboratory to point to, a result all the more interesting as being the immediate offspring of a renewed attention to the chemistry of the elements. The chemist has lately made diamonds; not indeed *carbon* diamonds, but *boron* diamonds, and *silicon* diamonds. Boron and silicon are so closely allied to carbon that it is a very significant fact that they are proved to exist in allotropic states precisely analogous to the adamantine, the graphitic and the amorphous modifications of carbon. For our knowledge of this we are indebted to the recent discovery that aluminium can be produced in the form of a workable and useful metal. Just as iron by a surcharge of carbon can, on solidifying, be induced to reproduce that carbon as graphite, so can boron and silicon be separated from aluminium in graphitic modifications, and from zinc in forms of octahedra of different crystalline systems indeed, but with physical properties closely resembling diamond. I will exhibit the images of these crystals presently by the aid of the electric light. This result is one which should certainly encourage the chemist to renewed efforts to produce the diamond, and to study those refinements of chemical and physical conditions on which doubtless the production of different allotropic states of matter depend.

You will now allow me at once to plunge to 320 years ago, into the centre of India and Indian history, and to transfer your attention to another but interesting subject—the history of the Koh-i-noor diamond. I believe there is

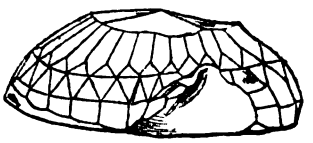
Fig. 3.



nothing about which so much mistake has been made as the true history of that diamond. Large diamonds are extremely rare. Here is a model of the Nizám diamond, which was one of the greatest perhaps ever known. This is that of the Orleans or Pitt diamond, the beautiful crown jewel of

France, the finest cut brilliant in the world. But I am now going to speak of the Koh-i-noor. This is the model of what it was in 1851, alas! not what it is now, for it has been cut. (*Fig.s* 3 and 4.) Some may look on this diamond as a bauble..

Fig. 4.



The Indian, looking back to the centuries of the past history of his fathers, calls it a talisman, the talisman of oriental empire. We here may not agree with either, but I hope to prove to you that we must see in it a wonderful historical monument. Its history, indeed, is almost the history of India, and its own records are told in part by authentic history, in part by tradition, and partly also in yet older days by that sort of tradition which is legend, and in which we lose sight of historical characters in the shadowy forms of heroes and demigods. Thus the fancy of the Hindoo identifies the old diamond of India with one of which the legend tells that it was discovered by a Zemindar, near Masulipatam, in the bed of the Godaveri, during the time of Krishna, 5000 years ago, and was worn by Karna, king of Anga, who fell in the great strife recorded in the Mahabharáta. It is then traced onward by the same wild sort of record to a great rajah of Usjein, in Malwa, who lived perhaps 57 B.C., but but whose very name, Vikramádytia, is a mythic one.

Tradition, however, of a more solid kind, asserts that the diamond was won by Alá-ud-dín from the rajah of Malwa, in the year 1304, which accords with Baber's statement that Alá-ud-dín was the first Pathán sovereign of Delhi who possessed it. Baber in his memoirs, which are about the most interesting documents ever written by a prince, and which are unquestionably authentic, states that after one of those great battles of Paniput, which in different centuries have decided the fate of India — after his battle of Paniput, he sent on his son Humayún to Agra, where he became possessed of "*one famous diamond, acquired originally by Sultan Ala-ud-din, and which was estimated to weigh* 8 *mishkals.*" I am now going to enter at once to hard figures and on what those 8 mishkals mean. Singularly enough the sultan Baber himself states in another part of his work, which has been hitherto overlooked in this discussion, that the mishkal, a Persian weight, actually weighed 40 ratis. The rati is this little red seed, the *abrus precatorius*, as this little bean from the carob bean, is the kharouba of Arabia, the Greek κεράτιον, and our *carat*. Well 40 of these ratis were equal to 1 mishkal. If you multiply 8 by 40 the result is 320 ratis. Thus "the famous diamond" weighed 8 mishkals, which is = 320 ratis = 40 mashas = 10 tanks = $3\frac{1}{3}$ tolas, as is shown in this table: —

8 Ratis	=	1 Mashah				
32 Ratis	=	4 Mashahs	=	1 Tank		
40 Ratis	=	5 Mashahs	=	$1\frac{1}{4}$ Tank	= 1	Mishkal
96 Ratis	=	12 Mashahs	=	3 Tanks	= $2\frac{2}{3}$ Mishkals	= 1 Tola.

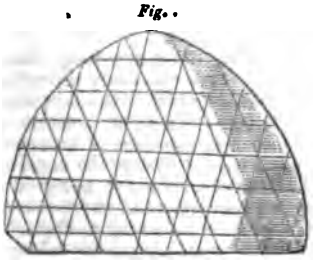
Now in 1851 the Koh-i-noor weighed 186·0625 carats = 589·82 troy grains, not carat grains, but troy grains (Professor Wilson, our eminent Sanscrit professor at Oxford, who has given the only good narrative of the old history of the Koh-i-noor, confounded these varieties of the grain in that narrative). If this famous diamond of Sultan Baber's autobiography weighed 8 mishkals, the question is what was a mishkal in Baber's time. In order to answer that question, I have gone through much of the numismatic and other lore bearing upon it which I could get access to for the period, including the Sassanian and the Græco-Roman empires to the present day, and I have availed myself of the materials and of the help of my colleagues in the coin room at the British Museum. One of the most remarkable records bearing on this subject is the ancient treatise at Makrizi. He states the exact relation of the mishkal to the denarius and dirhem, and the relation of the Syrian mishkal to the Greek mishkal in the times of the Caliphat, which Abúl-Fuzl states to be the same as that of the Indian to the Greek, and the result would be that the mishkal would weigh 74·2 grains. Taking the Koh-i-noor at 8 of these, it would weigh $187\frac{1}{2}$ carats. Now a modern Persian goldsmith's mishkal weighs exactly $74\frac{1}{2}$ grains, and the result of that would be 188 carats for the Koh-i-noor. The mercantile mishkal weighs 73·975 grains, giving for the Koh-i-noor 187 carats. The mishkal of Bussorah (the El Basrah of the "Arabian Nights," the ancient outport of Arabia on the Persian Gulf) gives 182 carats, and the modern Bokhara mishkal, which is the place from which Baber came, would give 179 carats, which is the lowest that I get, while the highest is $187\frac{1}{2}$ carats. Then I go on from the calculation of the Persian weight to that of the Indian weight, the tola, and I come to a very curious result, not quite so high, but still very remarkable. The Indian tola is a very ancient weight; it had been the standard of some of the ancient Indian coins long before Baber's time, and until Shír Shah's time was probably pretty uniform as a weight. Shír Shah changed the money standards from the mishkal (the Mahommedan weight) and from the old tola and adhali, to a new Hindoo standard, in which the tola became 186 grains. I will simply state that the result of calculations made from some splendid gold coins of Mohammed Tughlak enables us to take the old tola to the reign of Baber at a minimum of 173, and up to 174 or perhaps 175 grains. This gives our diamond a weight of from $182\frac{1}{2}$ to 185 carats. Now I venture to think that after these facts I am fairly justified in saying that the weight of the Koh-i-noor in the Great Exhibition, represented more accurately than any other diamond which is known the weight of the famous diamond which the Sultan Baber had, and to which the old legends and traditions as well as the authentic histories of India refer.

Now in 1675 a French traveller of considerable reputation, Jean Baptiste Tavernier, who was a diamond merchant, was in Delhi at the time Aurungzebe was king, and while his father, Shah Jehann, was his state prisoner. Shah Jehann had all his jewels in his prison with him, and thus while he had whatever enjoyment was to be derived from their possession, his son enjoyed the pleasures to be derived from the occupation of the throne. That he retained among these the most valuable of those that formed his personal property is proved by this anecdote. Shortly before the death of Shah Jehann, Aurungzebe sent to demand from his father those jewels which he retained, upon which Shah Jehann answered, that sooner than give them up he would smash every one of them in the mortars which he held ready for the purpose. Then the question was, how came Tavernier to have seen a vast diamond, which he describes, and which, from the account he gives of it, would have been, not a crown jewel of the empire, but a personal acquisition of Shah Jehann's; and if he saw only that one great diamond, where was the old "famous diamond"? It seems to me the true answer is that Shah Jehann had in his captivity with him the diamond whose history Tavernier gives, and that the one Tavernier saw was the old crown jewel, then for 360 years the property of the sovereigns of Delhi. Indeed history records that after Shah Jehann's death his private jewels were surrendered to Aurungzebe by his sister Jehanira. His death was in February 1666, and Tavernier saw the royal treasury in November 1665. On that occasion Aurungzebe sat on his throne, and the French diamond merchant was authorised to inspect his jewels. Among them he saw the large diamond in question. He describes the solemnity, the state, and precaution with which it was put into his hands, and $319\frac{1}{2}$ ratis he states to have been the weight of it; 320 ratis, you will remember, was the weight of the diamond which the Sultan Baber had. Tavernier describes it as a "*rose ronde*," that is, a rose cut stone, with the corners rounded, "*very high on one side*," and that is what we have

never seen in any other diamond than the Koh-i-noor. If we take the Koh-i-noor standing so, it is much elevated on this side. Then the description exactly accords with the description of Tavernier. And if it were set in that position, and so that the girdle shall come round in this direction, which is somewhat as it was set in Runjeet Singh's day, it is in such a position that two incisions which are in it are hidden, and a third comes into view. Now Tavernier's description of the diamond is this—he states that on the lower edge there is a little notch, and a small flaw inside of it. This would then be a precise description of the Koh-i-noor. The water, he says, is fine, and it weighs 319½ ratis. He then goes on with a long description of this stone, which, according to this account, had been found by a Persian adventurer, who got himself in a mess at the Court of Golconda, and who gave it to Shah Jehann to purchase his goodwill. Now there was the old diamond of Sultan Baber, which weighed 320 ratis, and Aurungzebe we see had one of 319½ ratis. Then where is the other? I think I have answered that question. We know that Aurungzebe must have had the original crown jewels, for the peacock throne which he sat upon was built up of them, and therefore the jewels which Shah Jehann had with him in the city of his captivity could hardly have been any of the jewels of the crown, but would have been, as I have said, his private cabinet; and he was said to be the best connoisseur of jewels in his empire. Tavernier therefore must have seen the old diamond of Baber, and not the Golconda diamond which bought the help of Shah Jehann for the Persian adventurer Ameer Jumla. But Tavernier, who could draw a diamond well, has given us a very bad sketch of the diamond he saw.

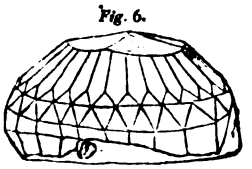
Now *these* are drawings of the Koh-i-noor, and that (*fig.* 5)

Fig.



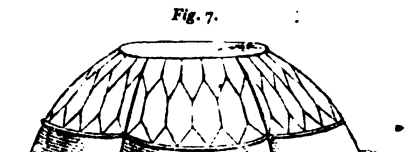
is Tavernier's drawing, which you will see is a very rough one indeed. *That* (*fig.* 6) is a view of the Koh-i-noor, taken

Fig. 6.



as accurately as it could be drawn, end on. *That* (*fig.* 7) is a drawing which Miss Eden drew of the Koh-i-noor when

Fig. 7.



it was in the possession of Runjeet Sing. They are sufficiently similar to be possible representations of the same diamond—they are sufficiently unlike to be considered no two of them as accurate representations of the same stone. Yet Miss Eden's is actually the Koh-i-noor, with the setting in which Runjeet Singh wore it.

That is the whole of the history of the Koh-i-noor that I wish to give you to-night. To continue it would be to follow it down through the long details of a wild and romantic history. But from that day to this the history is clear. It received its name from Nadir Shah, who, when India lay at his feet, met his half vassal, the Emperor of Delhi, who wore in his cap the great diamond of his fathers. Nadir saluted him, and exchanged turbans in sign of eternal amity. The Mound of Light then received its Persian name, and passed the Indus with its new master. It saw the rise, and helped the downfall of the Douranee empire, and passed by treachery, or even worse, into the clutch of Runjeet Singh With his descendants, the shadow of England passes over the Punjaub, and the one famous diamond of India falls into the hands of the conquerors from the distant west.

If there are any of you who would wish to remain, I will show you a few illustrations of those forms of boron and silicon to which I have alluded.

First of all, if you please, I will take boron. These hexagonal plates are the analogues of the graphitic form of carbon. There you can see the little hexagonal plates beautifully. In these images, again, you may see the lozenge shape of the outlines of the octahedra, first of the boron, and here of the silicon diamond. I may add to that a very curious fact. Dr. Faraday put into my hand, just before I entered the theatre, a round mass of boron that M. Dumas sent to him from Paris, precisely like that form of diamond which is called boart, and which consists of a confused congeries of crystals.

Now I propose to show you a few beautiful phenomena.

The learned lecturer then exhibited in the beam of the electric light a beautiful Maltese cross of diamonds, a beautiful large diamond briolet (a single stone) producing a most dazzling effect, and a chrysoberyl, which is surpassed in brilliancy and limpidity by no stone but the diamond itself. The effect of it, though brilliant in the extreme, lacked the glow which the diamond presented. Next the light blazed on a collection of the most beautiful coloured diamonds, beautiful not for their size but for their purity of colour and fine water, which Mr. Martin had been a long time collecting. Mr. Maskelyne then reflected the iridescent surface of a most beautiful opal upon the screen, and afterwards of a mass of opal. To convey anything like an adequate idea of any of these splendid phenomena is beyond the ability of pen or pencil.

CHEMICAL SOCIETY, *Anniversary Meeting*, 30 *March*.

Professor Brodie, *F.R.S. in the Chair.*

The report of the Council was read and adopted, and the following officers were elected for the ensuing year. President: Brodie, B. C., F.R.S. Vice-Presidents, who have filled the office of President: Brande, W. T., F.R.S.; Daubeny, C. G. B., M.D., F.R.S.; Graham, Thomas, F.R.S.; Miller, W. A., M.D., F.R.S.; Playfair, Lyon, Ph.D., F.R.S.; Yorke, Colonel Philip, F.R.S. Vice-Presidents: Frankland, E., Ph.D., F.R.S.; Jones, H. Bence, M.D., F.R.S.; Porrett, Robert, F.R.S.; Smee, Alfred, F.R.S. Secretaries: Redwood, Theophilus, Ph.D.; Odling, William, M.B., F.R.S. Foreign Secretary: Hofmann, A. W., LL.D., F.R.S. Treasurer: De la Rue, Warren, Ph.D., F.R.S. Council: Field, Frederick; Francis William, Ph.D., F.L.S.; Longstaff, G. D., M.D.; Marcet, Dr., F.R.S.; Mercer, John, F.R.S.; Noad, Henry M., Ph.D., F.R.S.; Normandy, A.R.L.M.; Roscoe, H. E., Ph.D.; Schunck, Edward, Ph.D.; Voelcker, J. A., Ph.D.; Warington, Robert; Williamson, A.W., Ph.D., F.R.S.

NOTICES OF PATENTS.

Hydro-Carburation of Peat.—Provisional protection only.—J. H. Johnson. *Communicated by M. de la Fenestre.*

As this invention only received provisional protection, we should scarcely have noticed it were it not that it shows that there is no process too absurd to be patented.

"The essential feature of this invention is the carburation, or hydro-carburation of peat, and other similar fuel, by a wet process, the object being to obtain as much hydrogen as possible in the fuel and expel the oxygen, which may be effected in various ways. According to one method, the peat is passed through bruising rollers, or other reducing apparatus, over a vessel containing ammoniacal water, which soaks the peat at the same time that it undergoes the bruising process, the object of the operation being to thoroughly impregnate the peat with the alkali. Another process consists in substituting two successive baths for the one above referred to, the one containing a ferrocyanide of ammonia and potassium, and the second a metallic chloride or acetate of iron. By this process also the peat may be charged with alumina, or any neutral body, by using a bath of dilute ammonia and a bath of acetate of alumina. The process may also be accomplished by the aid of fermenting agents, such as yeast, albumen, caseine, &c. The result of the action of the alkalies upon the peat is that the peat assumes the properties of an acid relatively to the bases, and offers facility for the introduction therein, either by simple or double decomposition, or (*sic*) of hydro-carburetted salts, or of greater or less quantities of carburets or hydro-carburets, and thereby augment considerably the combustible value of the fuel and its gas-producing powers, carburetted peat being found to produce as much gas and coke as pit coal." At last a full point! We never were more thankful for an opportunity to come to a full stop. Imagine ammonia, ferrocyanides, yeast, albumen, caseine, &c. as sources of hydrogen for gas. Acetate of alumina to yield a fixed residue as a source of coke. Peat assuming the properties of an acid—we are not forgetting the real peat acids. Does our inventor not know that nitrogen is not a great improver of illuminating gas? Does he not know that albumen is now at an almost fabulous price, owing to the quantities now used for mordanting the new colours? It is painful to see such processes seriously given to the world.

Manufacture of Metallic Compounds or Alloys. Robert Mushet.

This is a patent for procuring an alloy of tungsten and iron, or of tungsten, iron and manganese. Divesting the process of the verbiage common to patents, it simply consists in mixing various quantities of wolfram with hæmatite, specular, magnetic, or spathose iron ores, or, especially, granular hæmatites or iron sand. The patentee does not state the nature of the advantages he expects to derive from the process, but, nevertheless, he finds the best results to be obtained when the resulting alloy contains from half a per cent. to ten per cent. of tungsten. A tolerably wide range! The patentee also finds, as might have been expected, that the greater the per centage of tungsten, the greater the specific gravity of the alloy, which is not very wonderful when we remember that the specific gravity of tungsten is 17·6, while that of iron is only 7·8.

Utilisation of Madder Residues, by Prosper Faure *and* Jules Pernod, *Avignon.*

This is an attempt to convert to use as a manure the nitrogenous matters which combine with the sulphuric acid in the preparation of garancine. In washing away the acid from the garancine so large a proportion of water is necessary that hitherto, the fuel required to evaporate it off, has been more valuable than the resulting product. The patentees endeavour to get over this difficulty by an economical mode of applying the heat. They do not attempt to collect all the washings from the garancine, but only the first two or three, the rest being too weak to be used up economically. They employ a brick oven, similar to those used in the concentration of the solution of carbonate of soda in the process for manufacturing that article. But as the flame dashes over the fluid, the soot, &c. resulting from the combustion of the fuel becomes to a great extent deposited, and at the conclusion of the operation will be found in the residue. The latter consists of ulmine, saline matters of various kinds, and a certain proportion of ammoniacal salts. Of course a great excess of sulphuric acid is present, which the patentees propose to saturate with chalk or quicklime.

It is plain that the above process contains the elements of failure unless superintended with great care.

In the first place, it is questionable whether in these days of expensive fuel the residues will pay for the expense of obtaining them. It is true that the patentees use the surplus heat to dry the garancine, and this, to some extent, gives a favourable aspect to the affair. The excess of sulphuric acid is so great that it becomes necessary to saturate it, but the operation, unless conducted carefully, would cause the loss of the ammonia; in fact they should say *partially* saturate, for it is of great importance that a certain excess of acid should remain. It is worth considering whether finely pulverised bone ashes would not be better than chalk or quicklime to saturate the residue; the soluble phosphates produced would of course greatly add to the value of the resulting manure. The evaporation must, of necessity, be conducted with extreme care, for if it were attempted to evaporate ammoniacal salts to dryness by the process used for carbonate of soda, there would be great danger of volatilisation of the ammonia in spite of the presence of an excess of sulphuric acid.

There appears to be a mania among some persons for taking out patents. It is absolutely marvellous to observe the extraordinary things which some people consider worth the expense of a patent. There is, however, method in the madness of some of these patentees of queer processes. We have, before now, studied hard in the endeavour to extract something definite from the mass of technical verbiage with which a patent has been crammed, and we have been inclined to consider the patentee as having no distinct aim, until we have seen, sometime after, actions for infringements of the very patents we have fancied to contain nothing definite. This is, in fact, the true secret of such patents; they are taken out solely with the view of affording a pretext to claim damages from persons using processes which can be made to appear infringements. The above remarks are not intended specially to apply to any patent or patents noticed in this number of our journal.

CORRESPONDENCE.

Chemical Nomenclature.

To the Editor of the Chemical News.

Sir,—In your recent numbers I see that there has been some discussion upon the chemical nomenclature, and if too much has not already been said on the subject, I would beg to offer a few remarks. It must be acknowledged that the present nomenclature is very deficient, and that an entire change would be inconvenient if not almost impossible at the present moment; this will come in time, but I think that in the term nitrate of potassium, which after all is not so very different from the old name of nitrate of potassa, the ending *ate* is quite sufficient to indicate that the above-mentioned body contains a compound oxygenated radical NO_6, which replaces the chlorine in chloride of potassium, without introducing the semi-barbarous names of nitrationide

or nitrionide of potassium, which I believe was first introduced by Mr. Daniell; and it would require a much smaller exertion of the memory to understand that the terminations *ate* and *ite* show the existence of oxygenated radicals capable of replacing oxygen and chlorine, than to learn an almost new nomenclature. Thus a chloride contains the radical Cl, a chlorite the radical ClO_4, and a chlorate the radical ClO_6.—I am, &c.

H. M'Leod.

Salt Efflorescences.

To the Editor of the Chemical News.

Sir,—Having, at different times, examined several samples of "salt efflorescences" from buildings near the sea, I can fully corroborate the statement of Mr. Wentworth L. Scott, in your impression of the 24th, as to their composition. I have invariably found them to consist of sulphate of sodium, nearly pure, with only slight indications of lime or magnesia, very little chlorine, and no trace of nitric acid.

From numerous inquiries as to the ingredients composing the mortar or cement in these cases, I have been led to consider this salt as derived from the sea sand so extensively employed here; indeed, I have never found it on a building where any other sand was made use of.

From its efflorescent nature, it is only seen on fine dry days; the least approach of damp weather causes its rapid re-solution and absorption; indoors this alternation may go on for ten or twelve years, defying paper, paint, or any other covering; but exterior walls, I am informed, get rid of it in two or three years from exposure to the attrition of winds, fall of rain, and other atmospheric influences. It makes its appearance on cement much sooner than on mortar, in consequence of the quick drying properties of the former. It is also seen to a small extent on bricks prepared with sea sand; some of these were used in the construction of the Crystal Palace, and it becomes an interesting question whether sea sand also entered into the composition of the cement or plaster employed in the Pompeian and other courts. I may mention that, when plastering with plaster of Paris, the builders here are very careful to use only land sand, to avoid the increased efflorescence.

Perhaps Mr. Scott will state, if possible, whether the samples he examined could be attributed to what I consider to be their sole origin—the sea sand.—I am, &c.

E. C. C. Stanford, F.C.S.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

Acichloride of Selenium and Alum of Selenic Acid.—The acichloride of selenium is produced by the action of chloride of selenium on selenious acid. The two are heated together in a closed tube bent at right angles. The acichloride is volatised and condensed, and any excess of selenious acid is left at the lower end of the tube. Weber[1] describes the acichloride as a yellowish liquid fuming in moist air, having the sp. gr. 2·44, and boiling about 220° C. Its composition may be expressed by the formula $SeCl_2 + SeO_2$, according to which it will be represented as a combination of selenious chloride and selenious acid. The composition may be also expressed 2(SeClO), representing the selenious acid, in which 1 atom of O is replaced by 1 atom of Cl; or a selenious chloride in which 1 atom of Cl is replaced by 1 atom of O. Wurtz remarks[2] that the acichloride of selenium is evidently the analogue of the chloride of thionyle, which Schiff obtained by the action of perchloride of phosphorus on sulphurous acid, and he thinks it likely that the chloride of selenyle (acichloride of selenium) would be formed under the same circumstances.

[1] *Poggendorff's Annalen*, Bd. cviii. s. 613.
[2] *Répert. de Chimie*, Mars 1860.

Alum of Selenic Acid.—Mitscherlich has observed that the sulphates and seleniates are isomorphous, and resemble each other so much in their properties that they can only be distinguished by separating the selenium. This would lead us to suppose the existence of double seleniates corresponding to the alums. Weber has succeeded in forming beautiful crystals of seleniate of potash and alumina exactly resembling those of ordinary alum. He obtained these by neutralising 1 part of selenic acid with carbonate of potash, and 3 parts with pure hydrate of alumina. He then poured the two solutions together and allowed them to evaporate spontaneously. The crystals are more soluble in water than those of common alum. At a dull red heat the selenic acid combined with the alumina is completely driven off.

Solubility of Silica in Alcohol mixed with Hydrochloric Acid.—Winkler[3] observes that when Portland cement slag from furnaces, olivine, or other pyrogenous silicates in fine powder are added to alcohol saturated with hydrochloric acid, the silica is dissolved, and a transparent mobile liquid is obtained. The author supposes that this is a consequence of the silica absorbing the elements of alcohol, which in that case replaces water of crystallisation. Wurtz[4] thinks that silica, like the other acids, may be etherified under the influence of a mixture of alcohol and hydrochloric acids.

Nitride of Chromium.—Ufer[5] points out that nitride of chromium, prepared according to Schrötter's process, at a dull heat has the remarkable property of decomposing ammonia into its elements. Heated in the air it is changed into the green insoluble oxide of chromium. When fused with potash or carbonate of soda it is not acted on. Alkaline hypochlorites disengage nitrogen and form alkaline chromates. Heated with oxide of copper or minium it burns with a red flame and disengages nitrogen. Nitrate of potash decomposes it with violence, causing an evolution of nitrogen, and the formation first of oxide of chromium, and then of chromate of potash. Chlorate of potash acts still more violently. It is not acted on by hydrofluoric acid. Chlorine disengages nitrogen and changes it into chloride of chromium. Hydrochloric acid at a red heat changes it into the violet chloride of chromium and chloride of ammonium. Long exposure to heat in a covered crucible decomposes it.

Aceto-nitrates of Iron.—M. Scheurer-Kestner writes[6] that when ferrous acetate is boiled with an excess of acetic acid and nitric acid it is rapidly oxidised; but the quantity of nitric acid required is double that indicated by the equation:

$$2FeO.C_4H_3O_3 + C_4H_3O_3 + NO_5 = Fe_2O_3.3C_4H_3O_3 + NO_2.$$

When the solution is sufficiently concentrated by evaporation the bottom of the vessel becomes covered with needles of a blood red colour, which may be purified by washing with ether, and solution in boiling water. Their analysis conducts to the formula:

$$Fe_2O_3.NO_5.2C_4H_3O_3.6HO.$$

An aqueous solution of this salt is decomposed by boiling into nitric acid, acetic acid and oxide of iron. Another equivalent of nitric acid added to the preceding salt gives crystals of a deeper colour, the analysis of which does not lead to a rational formula.

By the action of acetic acid on the soluble basic nitrate of iron $Fe_2O_3.2NO_5$, small prisms are obtained whose composition is represented by the formula:

$$Fe_2O_3.2NO_5.C_4H_3O_3.3HO.$$

Compound of Bichloride of Sulphur and Perchloride of Iodine.—By passing a current of chlorine for a long time over a mixture of one part of iodine and two parts sulphur, M. Jaillard obtained a liquid which deposited beautiful transparent prismatic crystals of a reddish-yellow colour. They were extremely deliquescent and de-

[5] *Annal. der Chemie und Pharm.* Bd. cxii. s. 281
[6] *Répert. de Chim.* Déc. 1859.

composed with violence when brought in contact with water. In the presence of alcohol or ether they produced a great evolution of gas, hydrochloric acid and etherial vapours, the mixture became hot, and on cooling there only remained a little sulphur and protochloride of iodine. With sulphide of carbon, the bichloride of sulphur is separated, and the perchloride of iodine decomposed, the iodine remaining in solution, and the chlorine giving rise to the formation of a chlorosulphide of carbon.

The analysis of the crystals yielded M. Jaillard results which show that their composition is expressed by the formula $SCl + ICl_3$.[7]

II. ORGANIC CHEMISTRY.

Researches on Acetone.—In examining the liquids which remain after having submitted rough acetone to a temperature above 130°, M. Fittig could only obtain a single body with clearly defined properties. It is an oil identical with phorone $C_{18}H_{14}O_2$, which Gerhardt and Lies had discovered among the products of the dry distillation of camphorate of lime. Fittig obtained this body by submitting the residus of acetone to a series of fractional distillations and reserving the product passing between 200° and 205°. Its identity with phorone was established with great care. The author has, among others, obtained one of the most interesting products of the decomposition of phorone, viz. cumene, $C_{18}H_{12}$, which shows the possibility of preparing benzoic acid with acetic acid.[8]

Composition and Mode of Production of Gum. M. Frémy[9] has discovered that gum is a salt composed of an acid, which he calls *gummic* and lime. Gummic acid, he says, is derived from *metagummic* acid. The metagummic acid is isolated by pouring some thick solution of gum into sulphuric acid. The two are left together for some hours, when the metagummic acid is found on the top, forming a sort of membrane, which is insoluble even in boiling water. When heated, however, with traces of lime, soda, potash, or ammonia, it dissolves immediately, and remains in combination with the base, reproducing the gum. The insoluble part of cherry tree gum (cerasine) is acted on by alkaline carbonates, and gums are produced exactly resembling those obtained directly by the action of bases on metagummic acid. Dilute and cold acids decompose cerasine and eliminate the metagummic acid, which by the action of lime produces gum arabic. Cerasine then is a compound of lime and *metagummic* acid.

Bassora gum contains a substance analogous to but not identical with metagummic acid. With the alkalies and alkaline earths it forms gummy substances, soluble in water, insipid, uncrystallisable, and insoluble in alcohol like gum arabic, but precipitable by acetate of lead, which gum arabic is not.

III. ANALYTICAL CHEMISTRY.

Influence of Fatty Bodies on the Solubility of Arsenic.—In a long communication[10] M. Blondlot relates that a great number of experiments have shown him that the least contact of arsenious acid with a fatty body reduced the solubility of the arsenic in several liquids to the fifteenth or twentieth of what it otherwise would have been. He also confirms the efficacy of oily mixtures (such as was mentioned at p. 71, CHEMICAL NEWS) in the treatment of arsenical poisoning.

SCIENTIFIC NOTES AND QUERIES.

Electrical Decomposition of Compounds of Nitrogen.—SIR,—The discrepancy observed by your correspondent *E. G.* between the statements of Faraday and Grove as to the decomposition of nitrogen compounds, arises from his not distinguishing between the two forms of electricity, *static* and *dynamic*. "Ammonia, protoxide of nitrogen, &c. are decomposed by the *discharge*;" that is, by the passage of *sparks* of electricity of tension, proceeding either from a frictional machine or a Ruhmkorff coil (see CHEMICAL NEWS, p. 8). This effect is generally considered to be due to the *heat* of the discharge, or to be virtually a decomposition by ignition. Professor Faraday must either have expressed his meaning imperfectly or been incorrectly reported, since voltaic electricity *does* liberate nitrogen from many of its compounds (*e. g.* ammonia, nitric acid). The nitrogen, however, does not pass uniformly to either pole, and is only set free by the action of nascent oxygen or hydrogen, arising from the decomposition of water simultaneously present. Hence, in Faraday's language, nitrogen is not an "ion," and its compounds are said to be incapable of electrolytic decomposition in the stricter sense.—*F. W. G.*

Estimation of Carbon by Combustion.—SIR,—In burning, according to the usual method, a compound of an organic acid with a strong base, such as potass, a portion of the carbon remains in the combustion tube as an alkaline carbonate. How may the process be best conducted so as to avoid such a result?—*E. G.*

MISCELLANEOUS.

A Doctor and his Assistant.—Eugène Coulon, a man who once made some noise in Parisian society died recently in the Rue St. Honoré. He was born towards the end of the last century, and was the son of a provincial chemist. He came to Paris to study medicine, but he possessed great talents as a mimic, and in that way made his fortune. Coulon had been recommended to Alibert, by whom he was much liked, and whom he often accompanied in his visits to his patients and to his hospital. Alibert sometimes exercised his art in a singular way. At his hospital he would sometimes stand at the door of a ward, glance at all the beds, and without entering point to each occupant one after the other, saying, "ipéca, ipéca, ipéca," as many times as there were beds in each room. And ipecacuanha was given to each patient. At the next ward he would do the same thing, only changing the remedy. Coulon was so thoroughly master of the peculiarities of Alibert that he too would sometimes show himself at the door of a ward, and imitating the voice, the face, and the manner of his patron would say, "ipéca, ipéca, ipéca," so that when Alibert himself arrived the nurses would say, "Doctor, you have already made your visit." And Alibert would depart astonished that he had forgotten the fact.—*Athenæum.*

Malleable Iron.—A new and improved method of malleable-ising iron castings is announced in the New York *Tribune* to have been discovered by Professor A. R. Eaton of this city. It consists in exposing the castings to the contact of oxide of zinc, as a substitute for the oxide of iron in the furnace. It is stated that the employment of the oxide of iron which combines with the excess of carbon in iron castings, when long exposed to a red heat, leaves a spongy residium on the castings, which is obviated by the zinc oxide, because the zinc is volatile and passes off, leaving the oxygen gas to combine with the carbon in the iron.

ANSWERS TO CORRESPONDENTS.

*** In publishing letters from our correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

A Subscriber (Paisley).—Certainly; but the proportion varies according to circumstances, and can only be told by an analysis. It is usually from 50 to 60 per cent.

A Beginner.—All can be obtained at Knight's in Foster Lane. The price of Hemming's jet is 10*s*. we believe, and Daniell's something more. Platinum is sold by weight, and the price is now about 32*s*. per ounce.

Tyro is thanked; we did not see the paragraph, but will look for it.

W. J. J.—You must have a license for your still, and you will be under the supervision of the excise. Rice we believe has been used and found more expensive than corn. Thomson's is still the best book on the subject.

An Engineer.—The steel is heated to the temperature at which the blue tint is assumed, and then suddenly cooled.

M. A. B.—The work will receive early attention.

E. G.—Received and in type.

W. G.—Received.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Remarks upon the various Methods usually adopted for the Separation of the Alkalies from the Bases with which they are generally associated in Soils, Minerals, &c. by FREDERICK FIELD.

(*Continued from p. 194.*)

IN continuing the recapitulation of the various processes usually adopted for the estimation of the alkalies in minerals, &c. it will also be useful to point out one or two methods of great excellence which do not appear to be so generally employed as their merits would lead us to expect. The action of caustic baryta has already been discussed, and the disadvantages attending its use are not lessened by the employment of the nitrate, and are even augmented by that of the carbonate. Dr. Lawrence Smith, in an investigation upon this subject, first published in Silliman's *American Journal*, and reprinted in the *Chemical Gazette*, has done much in facilitating the fusion of the various silicates containing alkalies, and shown that by adopting certain methods the difficulties attendant upon this class of investigation can be exceedingly lightened, and the decomposition of the alkaline silicates very greatly facilitated. As the processes he adopts are now generally known, it will be merely necessary to consider their leading features and characteristics.

Dr. Smith first tried the fusion of the mineral under examination with carbonate of lime and fluor spar. Carbonate of lime *per se* acts with considerable energy upon the silicates, as it parts with its carbonic acid much more readily than the carbonate of baryta, the only obstacle to its use being the employment of a very intense temperature. Mixed with fluoride of calcium, which merely acts as a flux, the mineral and the lime are brought into intimate contact, and the difficulty is, to a great extent, removed.

The substance to be examined, finely pulverised, is mixed with from four to five parts of pure precipitated carbonate of lime and its own weight of fluor spar, and introduced into a platinum crucible capable of holding three times the bulk of the mixed powder. It is then exposed, with the usual precautions, to a bright heat for three quarters of an hour.

By this means Dr. Smith found that the most refractory silicates were entirely decomposed. After cooling, the contents of the crucible are digested with one part of hydrochloric acid and two of water, until dissolved, and carefully evaporated to dryness, an operation far easier than after the soda fusion, as the evaporation proceeds more quietly and without decrepitation. A little hydrochloric acid is added to the dry mass, and subsequently water, when heat is applied, and the liquid boiled for a few minutes. A slight excess of concentrated solution of carbonate of ammonia is introduced, and the precipiate, which is allowed to subside, is filtered off. The solution contains chlorides of ammonium, magnesium, and a little chloride of calcium, and is then partially evaporated on a sand bath.

In order to avert the great inconvenience which is always experienced in the evaporation of the solution of chloride of ammonium, Dr. Smith takes advantage of a fact described by himself some short time previously, viz. the decomposing effect produced by heating sal-ammoniac with nitric acid. About three parts of nitric acid are added to every one of sal-ammoniac present, the solution warmed gently, and below the temperature of boiling water decomposition, accompanied with considerable evolution of gas, takes place with great rapidity. By this means much trouble is avoided, and the evaporation proceeds quickly and rapidly; when dried, the residue is dissolved in a little water, lime water is added, the liquid is boiled and filtered, the filtrate treated with carbonate of ammonia to separate the lime, and again evaporated to dryness. Dilute sulphuric acid is now added, the nitric and hydrochloric acid expelled by heat, and the alkalies left in the state of sulphates. For the conversion of the sulphates into the chlorides, Dr. Smith prefers the acetate of lead to chloride of barium; this reagent is added in slight excess, in order to precipitate the whole of the sulphuric acid; the filtrate, after warming, is treated with sulphuretted hydrogen, the sulphide of lead removed by filtration, excess of hydrochloric acid added to the acetates of the alkalies, and the liquid evaporated to dryness. This process, although excellent, has since been improved by the same chemist. Dr. Smith found that silicates could be fused still more easily by mixing them, in a finely divided condition, with rather more than 0·5 their weight of chloride of ammonium and 5 to 6 of carbonate of lime. After forty minutes strong heat in a platinum crucible the mineral is entirely decomposed. "There is no silicate," observes Dr. Smith, "which, after having undergone this process, is not easily dissolved by hydrochloric acid."

But perhaps the most important point in this method is the facility with which the alkalies can be at once separated from the other bases without subjecting the solution to numerous processes before these bodies can be obtained in a state for estimation. After the mineral or other product under examination is perfectly decomposed by fusion with the required proportions of carbonate of lime and chloride of ammonium, the mass is heated with water until thoroughly disintegrated, when it is thrown upon a filter and thoroughly washed. The filtrate contains merely the chlorides of the alkalies, a little chloride of calcium, and caustic lime. A small quantity of carbonate of ammonia is added to precipitate the two latter substances, the carbonate of lime separated by filtration, the filtrate evaporated and gently ignited; the alkalies remain as chlorides.

Few processes in chemistry can be simpler than this. The potash and soda are both brought into a soluble condition, and are easily and satisfactorily removed from the other bases.

As far as my own experience extends, Smith's method

is very superior to that proposed some time ago by Wurtz, viz. the decomposition of siliciferous mineral by means of chloride of barium, or a mixture of that salt with chloride of strontium. I have tried few experiments with the mixture just alluded to, but have found great difficulty in decomposing silicates by the simple admixture of chloride of barium.

In the beginning of this short notice the disadvantages of a very high temperature when caustic baryta was employed were pointed out, although in some very refractory silicates there is no doubt an intense heat is occasionally required for their perfect decomposition, even at the risk of endangering the crucible. But in soils and most metallurgic products, slags, &c. no very prolonged action or excessive degree of heat is necessary. In two equal quantities of the same soil, one mixed with four times its weight of caustic baryta, and the other with four times its weight of chloride of barium, and each subjected for five and twenty minutes to a gas flame urged by bellows, the former was found to be entirely decomposed, becoming perfectly soluble in hydrochloric acid, and after evaporation forming a clear transparent jelly, whilst the latter, on the addition of dilute acid, left a large deposit of undecomposed mineral. There is no doubt whatever that by a more prolonged action all the earthy matter would have been decomposed by the chloride of barium, but as far as I can see, in ordinary cases of analyses, this substance has no superiority over caustic baryta. The mixture of the chlorides of strontium and barium is doubtless far more fusible than the latter *per se*. The last portion of Dr. Smith's method appears somewhat tedious. The decomposition of the nitrates and chlorides of the alkalies into sulphates, the addition of acetate of lead for the formation of soluble acetates and an insoluble sulphate, and the separation of the lead by hydrosulphuric acid. If oxalic acid were employed to the mixed chlorides and nitrates, an entire decomposition of the latter would occur, and also if the former by more prolonged action, which is however needless, as the alkaline metals are required in the state of chlorides. One or two digestions with a strong solution of oxalic acid, evaporation and ignition, would yield a mixture of the carbonates and chlorides which of course could be immediately converted into the latter without the aid of hydrochloric acid.

Schaffgotsch, quite recently, assures us that a slight excess of caustic ammonia added to a solution of sesquicarbonate of that alkali completely separates magnesia as a crystalline precipitate, having the formula $NH_4O.CO_2+MgO.CO_2+4HO$, a compound requiring 60,000 parts of the precipitant for its solution, and leaving 15·6 per cent. of residue after ignition, which, if the above formula be correct, would be pure magnesia. The author recommends the separation of magnesia from the alkalies by this way, but should the compound be soluble in chloride of ammonium, this body would have to be expelled before the addition of the sesquicarbonate.

In concluding the foregoing brief criticisms upon the various modes of separating the alkalies from other bases in siliciferous compounds, nothing strikes me as so important as the method proposed by Dr. Smith, for extracting the alkalies from the fused mass by aqueous solution; thus freeing them at once from the great bulk of the other earthy bases. There is little novelty in this, as that chemist observes, as Fuchs long ago used a similar method for extracting lithia from lepidolite, and many methods have been proposed, and some adopted for the extraction of potash on the large scale, by fusing felspathic or other rocks, rich in that alkali, with lime or carbonate of baryta, and subsequent digestion with water.

Now in chemical analysis when caustic baryta is employed for the decomposition of the silicates (provided the decomposition be perfect), it would appear that the alkalies could be entirely extracted by water alone, without the aid of an acid whereby other bases are dissolved, and have again to be separated from those which are sought after. The filtration would certainly be long, as the slowly soluble baryta would cause an alkaline solution to pass through the filter for a considerable period, and until the last trace of alkalinity has disappeared no certainty can be attached to the removal of the last traces of potash or soda. This could be overcome, nevertheless, by the conversion of the baryta into carbonate by a current of carbonic acid, which would not interfere with the solubility of the alkalies. Experiments, I believe, are required to guarantee the methods just proposed. I am not aware at least of any investigations upon this particular subject.[1]

TECHNICAL CHEMISTRY.

On the Use of Lime as a Disinfectant of Sewage; and on the Necessity for and Advantages to be obtained from Perchloride of Iron.

Drs. Miller, Hofmann, and Frankland have addressed a report on the above subject to the Metropolitan Board of Works, from which we extract the following:

By the use of lime and chloride of lime, as was practised during the course of last summer, there can be no doubt that the state of the river was decidedly improved. The temperature of the river was for a whole month above the hottest point which it attained in the previous summer, the rainfall of the preceding autum and winter was decidedly deficient, and the quantity of sewerage matter was greater than in former years, yet according to the testimony of many who made it their particular object to observe this point, the offensive condition of the river was mitigated.

Considering that the pollution of the river is annually increasing, owing to the gradual conversion of cesspools into waterclosets, and the extension of the system of drainage, they are decidly of opinion that some means ought to be adopted with a view of endeavouring to mitigate the offensive condition of the river in hot weather.

The lime and chloride of lime were at the time they were employed last year the best deodorising agents that could be obtained in sufficient quantity, and at reasonable cost to supply the demand which suddenly arose.

During the summer a careful investigation was made upon the use of perchloride of iron. These experiments pointed out this agent as the one which, taking all circumstances into consideration, is best adapted to operations of such magnitude.

These experiments, however, were made with stagnant sewerage products, confined in tanks, in a manner corre-

[1] In allusion to the separation of magnesia from the alkalies by means of oxalic acid, it appears from a paper published in *Poggendorff's Annalen*, xcv. p. 401, and *Chem. Gazette*, xiii. p. 357, that Weeren evaporates the ammonical solution of the alkalies and magnesia, freed from lime by oxalate of ammonia, to dryness, raises the temperature gradually to a red heat, with the previous addition of dry carbonate of ammonia, and washes out the carbonates of the alkalies. In this case however they were dissolved originally in nitric acid, and the solution was free from hydrochloric acid. Weeren also adopts the method of Deville, who adds crystals of oxalic acid to the ignited mass, and again raises the substance to a red heat.

sponding to that in which the matters will have to be dealt with when the system of main drainage, at present in process of construction, is completed. The perchloride proved perfectly successful under these circumstances in arresting putrefaction for at least nine days during the hot period in July last; but it must be borne in mind that the conditions under which the perchloride can at present be applied are essentially different, since it must be mixed with the liquids whilst they are flowing through the sewers.

Nevertheless, there is every reason to expect that the application of perchloride of iron to the contents of the sewers as they flow outwards will be attended with a benefit greater than that which was found to be the result of the use of the chloride of lime in the course of last summer.

They are further of opinion that in order to derive full benefit from the use of this, or of any other deodorising agent, its application at the outfall of the sewers should be commenced some weeks before the hot weather sets in; not later, for example, than the 1st of May.

In conclusion, they wish to state distinctly that they believe that the use of perchloride of iron will effectually arrest the putrefaction of the matters daily contributed by the sewers, and go far towards reducing the condition of the river to that in which it would be if the sewerage products were for a time diverted. But they do not anticipate that the use of the perchloride, or indeed of any other disinfecting agent, in the only manner which is at present practicable, will altogether prevent decomposition in the body of water and mud already in the river.

PHARMACY, TOXICOLOGY, &c.

On some of the Chemical Reactions of Strychnia, by T. G. Wormley, *M.D.*

In the following paper it is proposed to give the result of some experiments in regard to the relative value of the various tests which have been proposed for the detection of strychnia.

The various solutions were made with great care from pure strychnia, generally dissolved in just sufficient quantity of dilute acetic acid, and the reagents were generally applied by means of a glass rod dipped in a saturated solution of the reagent, to a *single drop* of the strychnia solution, delivered upon a glass side, from a graduated burette which furnished a grain of fluid in each drop. Therefore, each drop contained an amount of pure strychnia, corresponding to the fractional dilution of the solution.

To prevent repetition in giving the various tests, the amount of strychnia operated upon will frequently be stated simply in the form of a fraction, it always being understood to imply the fractional part of a grain of strychnia, in one grain of water.

1. Ammonia.—1. $\frac{1}{100}$th grain of pure strychnia in one grain of water, gives with ammonia an immediate white precipitate, at first amorphous, but very soon it begins to assume a crystalline form, and in about three minutes the drop becomes a solid mass of lengthened prisms.

2. $\frac{1}{500}$ gives no immediate precipitate, but in a few seconds beautiful stellate crystals begin to form, which very soon become abundant.

3. $\frac{1}{1000}$ behaves much the same as 2—not so abundant.

4. $\frac{1}{2000}$, with the microscope, crystals begin to form in about a minute; in three minutes they are very obvious to the naked eye. If the drop be rubbed with the glass rod, rings of granules are very obvious to the naked eye in a few seconds, and the ppt. is much more abundant than when not thus treated.

5. $\frac{1}{5000}$, no indication after stirring for several minutes, except when viewed with the microscope, a few granules appear.

From the above, the limit of the test, when applied to a single drop, is when it holds in solution $\frac{1}{2500}$th its weight of strychnia.

2. Potash.—This reagent behaves much the same as ammonia, its limit being about the same. In applying this test it is very important that the proper quantity of the reagent be added, for if either too much or too little, no ppt. will be produced.

3. Carbonate of Potash.—1. $\frac{1}{100}$th grain of strychnia gives an immediate white precipitate of star-like crystals, which will redissolve if a sufficient quantity of the reagent has not been added.

2. $\frac{1}{500}$, in a few seconds small granules, prisms, and a few star-like crystals begin to form, which soon become rather abundant.

3. $\frac{1}{1000}$, in a few seconds lengthened granules may be observed with the microscope in a few minutes they are obvious to the naked eye.

4. $\frac{1}{2000}$, after a few minutes small granules are very perceptible.

5. $\frac{1}{5000}$, after several minutes, no indication with the microscope.

4. Carbonate of Ammonia.—In $\frac{1}{100}$ and $\frac{1}{500}$ solutions, the same results as with carbonate of potash. In a $\frac{1}{1000}$th solution, no indication after 15 minutes.

5. Iodide of Potassium.—1. $\frac{1}{100}$th, solution in a few seconds gives a white crystalline ppt. of tufts of long prisms.

2. $\frac{1}{500}$, it is several minutes before crystals begin to form; if the solution be stirred, however, they begin to appear in about 2 minutes.

3. $\frac{1}{1000}$, by stirring, crystals begin to appear in about 5 minutes.

4. $\frac{1}{2000}$, crystals begin to appear in about 7 minutes.

5. $\frac{1}{5000}$, with the microscope crystals can be seen in 10 minutes, in about 20 minutes they are just perceptible to the naked eye.

6. Sulphocyanide of Potassium.—1. $\frac{1}{100}$, gives an immediate mass of white crystals.

2. $\frac{1}{500}$, in a few seconds the crystals are very abundant.

3. $\frac{1}{1000}$, by rubbing, in a few minutes crystals begin to form.

4. $\frac{1}{2000}$, after several minutes, a few crystals may be observed upon the border of the drop with the microscope.

7. Tannic Acid.—1. $\frac{1}{1000}$, gives an immediate white curdy precipitate.

2. $\frac{1}{2000}$ gives very satisfactory results.

3. $\frac{1}{3000}$, after a few minutes the ppt. is quite perceptible.

4. $\frac{1}{4000}$, after several minutes it is just possible to observe a white cloudiness.

The satisfactory limit of the test is when it is applied to a drop of fluid holding in solution $\frac{1}{2500}$th its weight of strychnia. The ppt. is very soluble in acetic acid; and if obtained from dilute solutions, it is also soluble in a drop of potash, giving a red liquid; but when produced from strong solutions, the ppt. will not all dissolve in a drop of potash solution.

(To be continued.)

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

Friday, 30 *March* 1860.

On Acids and Salts, *by* Wm. Odling, *Esq.*, *M.B. F.R.S. Honorary Secretary of the Chemical Society.*

Lord Wensleydale *in the Chair.*

I do not conceal from myself that the story I have to tell you this evening is of a somewhat abstract and complicated character; but, favoured with your kind attention, I do not despair of making it interesting to you. I say this to dispel any alarm which the array of diagrams behind me might possibly induce in your minds. The subject I have undertaken to bring under your notice is one of so extensive a nature, that I can hardly venture to occupy much of your time with preliminary considerations. I think it necessary, however, to make a few remarks upon the position from which I propose to regard my subject, and consequently the position from which I wish you to regard it. In the early period of modern organic chemistry what is called the electro-chemical theory was in full authority: every chemical compound was a dual compound, it was either a binary compound, or was made up of two or more binary compounds. Thus lime was a binary compound of calcium and oxygen, sulphuric acid was a binary compound of sulphur and oxygen, and this body, sulphate of lime, was made up of the two binary compounds lime and sulphuric acid; and so it was with all compounds at that time known to chemists. Now this electro-chemical theory, although quite inadequate to explain many phenomena, and only adapted to others by being subjected to most vigorous and remorseless contortions, answered the purpose of mineral chemistry pretty well on the whole, and was useful in its day by enabling chemists to associate a great number of different compounds under one common point of view. It was natural therefore that chemists, deciphering the unknown by the known, should, in their earliest attempts to penetrate into the recesses of organic chemistry, have relied upon this selfsame theory as the great and only exponent of all mysteries of composition. In accordance with these views alcohol was represented to be a combination of oxide of ethyl, or ether, with oxide of hydrogen, or water; it was in fact the hydrated oxide of ethyl, precisely as slacked lime was the hydrated oxide of calcium; and similarly the ethers were represented to be salts of the oxide of ethyl, precisely as lime salts were represented to be salts of the oxide of calcium. So far there was no great harm done: alcohol and the ethers, although very different from hydrated bases and salts, have certain properties in common with them, and are capable of undergoing certain more or less of analogous reactions. But in many of its applications, and particularly in reference to what are now called substitution compounds, the electro-chemical theory failed altogether, even in the hands of its most accomplished expounder, the great Berzelius. Let me give you one or two instances of its failure. Here is the formula written up for indigo $C_{16}H_5NO_2$; now when this blue indigo is acted upon by oxidising agents, that is substances capable of giving up their oxygen, it becomes converted into a crystalline body of a yellowish red colour known as isatin. We have here in this vessel a solution of indigo, and if we add to the indigo some nitric acid, the nitric acid being an oxidising agent oxidises the indigo. The colour you see is disappearing, and that which was blue indigo has become yellow isatin. Now isatin differs in composition from indigo in this particular, that whereas indigo only contains two atoms of oxygen, isatin contains four. In this table I am purposely using the atomic weights of Berzelius. Now when isatin is acted upon by chlorine, it loses one of its hydrogen atoms and acquires an atom of chlorine in exchange, so as to become chlorisatin, and this, when further acted upon by chlorine loses another atom of hydrogen and gains another atom of chlorine so as to produce bichlorisatin. These three bodies, isatin, chlorisatin, and bichlorisatin, although so different in composition, present the most remarkable similarity to one another; you cannot distinguish them by sight, and nothing less than an ultimate analysis, utterly breaking up the compounds, can identify them one from the other; they are all three yellow-red bodies, they all crystallise in the same form, they are all insoluble in water, they are all soluble in alcohol, and all unite with alkalies to form corresponding salts. Now the formulæ here adopted

Chlorine Substitution.		
$C_{16}H_5$	NO_2	Indigo.
$C_{16}H_5$	NO_4	Isatin.
$C_{16}H_4Cl$	NO_4	Chlorisatin.
$C_{16}H_3Cl_2$	NO_4	Bichlorisatin.

show the relation of these bodies to each other, but, according to the electro-chemical theory, which professed to explain their real nature, they were represented as follows.

$C_{16}H_5N.O_4$	Oxide of Inden.
$C_{16}H_4N.O_3 + ClO$	Basic Hypochlorite of Porrinden.
$C_{16}H_3N.O_3 + 2ClO$	Neutral Hypochlorite of Flavinden.

Isatin was a binary compound of oxygen and inden, the first substitution product was a basic hypochlorite of porrinden, and the second substitution product, a neutral hypochlorite of flavinden. The first was an oxide of inden which no one had ever seen, the next was a hypochlorite of porrinden, which no one had ever seen, and the third was a hypochlorite of flavenden, a body equally hypothetical with its two predecessors. I may take another illustration from the oil of bitter almonds, or benzoic aldehyd, $C_{14}H_6O_2$. If you act upon this body with chlorine you take out one of the hydrogen atoms, and introduce in its place an atom of chlorine so as to get the body chloro-benzoic aldehyd, $C_{14}H_5ClO_2$. Now how do you think these two bodies were represented by the electro-chemical theory? The first by the formula $C_{14}\ H_5\ O + HO$, and the second by the formula $2\ (C_{14}\ H_5.\ O_3) + C_{14}\ H_5\ Cl_3$, which last body, $C_{14}\ H_5\ Cl_3$, has not been seen up to the present day. But the discoverers of chloro-substitution would not allow organic chemistry to be simplified in this fashion. The electro-chemical theory had failed egregiously in reference to chlorine substitutions; it had proved inadequate to explain and associate the multitude of new results so unceasingly produced, and had to give way to the theories of substitution, of types of decomposition, of organic series, and of multequivalent radicles, by the aid of which we are enabled in the present day to explain the relations and composition of those numerous complicated bodies by which the domain of organic chemistry has been so continuously enriched. Seeing, then, the light which these modern views have thrown on bodies whose constitution the electro-chemical theory left completely in the dark, it was only natural to inquire whether these selfsame views might not throw some additional light on the simpler compounds of mineral chemistry, and particularly upon those compounds known as acids and salts which have hitherto constituted the strongholds of electro-chemistry. Now it is to this inquiry I propose to direct your attention this evening. I wish to illustrate to you the nature of our old acquaintances, the mineral acids and their salts, by the light of modern doctrines. And I think I may venture to enlist your sympathies so far as to say that these doctrines are likely to have considerable permanence. Doubtless they will be absorbed in a higher generalisation, but so far as they go, they are, I believe, true; they are theories of observation rather than theories of causation, to be compared rather with Kepler's laws of planetary motion than with Newton's theory of gravitation.

The two principal laws or doctrines of which I shall avail myself this evening have reference to series and substitutions. Now the doctrine of series amounts to this, that if you search out among the immense number of bodies known to chemists, you will find a great number which are capable of being arranged in a series, the successive members of which differ from each other in composition by a

common increment, and that the bodies thus associated in composition are also associated by certain relations in their properties. We have homologous series, isologous series, and various other series, all differing from each other in the nature of their increments; but, in any series of bodies differing from one another by a common increment of composition, we find a distinct relation in properties, the nature of the relation varying with the nature of the series.

Now with regard to substitution, chemists admit at the present day that in the greater number of instances it is not possible for them to ascertain the arrangement of the atoms which enter into the constitution of a compound. Hence they no longer represent alcohol as the hydrated oxide of ethyl; at any rate not as a statement of its actual constitution. But they admit that it is very readily possible to know that the arrangement of the atoms in a certain compound is the same as that in some other compound derived from it by equivalent substitution.

Thus I have here a solution of oxalic acid; if to that solution I add a solution of a salt of copper, I get an abundance of a pale green precipitate. The formula for oxalic acid is $C_2H_2O_4$, and the formula of the green precipitate, which is oxalate of copper, is $C_2Cu_2O_4$. They differ in this, that the two atoms of hydrogen in the oxalic acid do not exist in the oxalate of copper, but are replaced by the two atoms of copper. Oxalate of copper is a substitution product of oxalic acid. Again, we have here the formula for benzoic acid, $C_7H_6O_2$, and also that for benzoate of sodium, $C_7H_5NaO_2$, obtained by abstracting an atom of hydrogen from benzoic acid, and supplying its place by an atom of sodium. If we act upon this benzoate of sodium by means of chlorine gas, we get a certain action which results in the production of chlorobenzoic acid, $C_7H_5ClO_2$, a compound that differs from benzoic acid in this particular, that benzoic acid has six atoms of hydrogen, while chlorobenzoic acid has only five atoms; and in the place of the missing hydrogen atom an atom of chlorine. Let us take another illustration. I am here acting upon acetic acid by alcohol, and I get in that receiver a body termed acetic ether. Now the difference between acetic acid and acetic ether is of a somewhat different nature to that subsisting between the other normal and derived bodies. Acetic acid has lost an atom of hydrogen and gained a compound substance called ethyl in its place. $C_2H_4O_2$ has become $\cdot C_2H_3EtO_2$. I may give you another mode of substitution. In the bottom of this jar is a small quantity of a substance, a species of kreasote, known by the name of phenic acid, C_6H_6O. Now when I act upon this body with a little strong nitric acid, I obtain a very energetic reaction, which results in the formation of trinitrophenic acid, $C_6H_3(NO_2)_3O$. The action was rather more violent than I expected, although I anticipated that the two bodies would react somewhat violently. The compound that we acted upon is phenic acid, and the compound that resulted is trinitrophenic acid, differing from the original body in this particular, that in it we have three atoms of hydrogen less, and in the place of those three atoms of hydrogen we have acquired three atoms of a compound of nitrogen and oxygen, known by the name of pernitric oxide.

I might refer to many other varieties of substitution, but the only substitution products I shall have occasion to refer to in illustration of my series of mineral acids are those which I have just exemplified to you, namely, metal-substitutions, chlorine-substitutions, ether-substitutions, and nitro-substitutions. The great service of those substitution compounds to us is this: — I want to explain to you the nature of series, and there are scarcely any two series complete, but the gaps which exist in them can be filled up by analogous substitution compounds. In several cases where I cannot put the acid into my series, I shall put the metallic representative, or the chloro representative, or the ethyl representative of that acid.

Now then for our series. The first member to which I will direct your attention is this,—muriatic acid or chlorhydric acid. In the first place this body has an extremely simple constitution; in the next place, all the world is agreed as to what its constitution is. It consists of one atom of hydrogen, and one atom of chlorine. This white block represents the bulk of one grain of hydrogen, and this green block represents an equal bulk of chlorine; that is a quantity of chlorine which weighs 36 grains, so that the two elements unite in proportion of atom to atom, bulk to bulk, 1 grain to 36 grains. Muriatic acid ordinarily exists as a gas. We have here a tube full of it. If I allow water to gain access to the gas, so extreme is the affinity of the one for the other that the water will gradually rise in the tube and absorb all the gas. There, it has risen nearly to the top already, and the solution thus formed is ordinarily known as liquid muriatic acid, which is a solution of muriatic acid gas in water. Now, in this limb of the U tube is a certain quantity of muriatic acid gas, and if I act upon it by some readily oxidisable metal heated to redness, the metal takes away the chlorine and leaves the hydrogen. We shall make this iron wire red-hot by means of the galvanic current, and then you will observe the change that takes place. There: now I am going to pour mercury into this limb to bring it to the original position of the experiment, that is to say, that the mercury in the two limbs shall be at the same level. Now, the mercury originally was down to here. We had that quantity of gas; you observe the quantity of gas has diminished to this point. I fear it may not be very visible at a distance. On cooling this residual gas, the decrease will be still more marked, and in the course of a short time, as soon as this space gets thoroughly cool, you will find that one half of the original bulk of the gas has disappeared — that one half being chlorine, the remaining half being hydrogen. This is a very important point to bear in mind. Chlorhydric gas has this characteristic property—it is capable of yielding up one half of its volume of hydrogen; two volumes of chlorhydric acid yield one volume of hydrogen, and this property pertains to fluorhydric acid, bromhydric acid, and to iodhydric acid. Two volumes of any of these gases are capable of yielding one volume of hydrogen, and this property pertains to no other body with which chemists are acquainted, and is therefore a strong reason for associating the four bodies one with the other.

HF Fluorhydric acid.
HCl Chlorhydric acid.
HBr Bromhydric acid.
HI Iodhydric acid.

Now, if we take chlorhydric acid and oxidise it, one of two things may happen. We may oxidise the hydrogen into water and leave the chlorine, or, if we use sufficient oxygen, we may, by operating in a particular manner, oxidise both elements together—thus, we write muriatic acid HCl, and if we take an insufficient quantity of oxygen, that is, if we take only one atom of oxygen to two of muriatic acid, we get the reaction $Cl_2H_2 + O = Cl_2 + H_2O$; that is, if we take an insufficient quantity of oxygen we get the hydrogen oxidated into water and the chlorine set free; but if we take a sufficient quantity of oxygen we get the reaction $ClH + O = ClHO$, the chlorine and hydrogen being oxidated conjointly into hypochlorous acid. Here is the experiment being performed: we have in this U tube muriatic acid HCl, through it we force a current of air, the air takes up the vapour of the acid and passes with it through this retort, containing a powerful oxidising agent, namely, permanganic acid or, what comes to the same thing, a mixture of sulphuric acid and permanganate of potassium. The result is a new oxidised product, or oxide of chlorhydric acid, known by the name of hypochlorous acid HClO. Now this body has not been satisfactorily isolated; it is known only by its solution and by its salts; but its composition has nevertheless been accurately determined. It consists of one atomic volume of hydrogen, one atomic volume of chlorine, and one atomic volume of oxygen, 1 grain of hydrogen, 36 grains of chlorine, and 16 grains of oxygen. Hypochlorous acid is a very interesting body: it is a very powerful bleaching agent.

We have here a solution of it. You see its bleaching action is very rapid; in the course of a few minutes the pattern of the print will have entirely disappeared. Hypochlorous acid HClO, is formed from chlorhydric acid HCl, by the addition of oxygen, and conversely chlorhydric acid is formed from hypochlorous acid, by the abstraction of oxygen. Hypochlorous acid, when boiled, undergoes a very curious change: it becomes chloric acid, $HClO_3$. We have a somewhat complex decomposition, from which this new body, chloric acid $HClO_3$, results. Now, when this chloric acid, which we have here, is deoxidated by means of nitrous acid, it is converted into chlorous acid, $HClO_2$, and when oxidated at the positive pole of a voltaic battery it becomes perchloric acid, $HClO_4$.

HCl	Chlorhydric acid.
HClO	Hypochlorous acid.
$HClO_2$	Chlorous acid.
$HClO_3$	Chloric acid.
and $HClO_4$	Perchloric acid.

Here, then, as shown in the table, we have a series of acids all expressed in the simplest possible formulæ, and arranged in a series, the successive members of which differ from one another in composition by an increment of one atom of oxygen. They are all convertible into one another by mutual metamorphosis; and, although separated widely in every chemical treatise that has been hitherto written, constitute a natural series of chemically associated bodies. Perchloric acid, the last member of the series, has a very curious action upon organic bodies, which I am able to show you. I have here some perchloric acid and aniline; and when the two bodies are heated together for a little time they undergo a very striking decomposition. The action will be indicated in the beginning by a little crackling, then by the production of a flame in the interior of the tube, and a sudden explosion.

We must now pass on to the next body on our list, sulphydric acid, which is a gas like chlorhydric acid. If we act upon it by red-hot iron we take away the sulphur and leave the hydrogen; and that we will now do. We will make the wire red-hot in this U tube containing the sulphydric acid; but mark the difference; in this case there is no alteration of bulk; there is an alteration of bulk depending upon the increase of temperature; but as soon as that increase of temperature has subsided, you will notice no alteration whatever in the bulk of gas. We have here a class of bodies, two volumes of each of which yield only one volume of hydrogen, namely, HF, HCl, HBr, and HI, as we have already observed. We have here another class of bodies, two volumes of each of which yield two volumes of hydrogen:

H_2O	Water.
H_2S	Sulphydric acid.
H_2Se	Selenhydric acid.
H_2T	Tellurhydric acid.

A given volume of any one of these last gases or vapours contains exactly twice the quantity of hydrogen that the same volume of any of the first class of gases contains; and we express this difference in their symbolic formulæ which we write with two atoms of hydrogen. I might illustrate to you the propriety of assigning this bihydric formula to water, by means of the well known experiment of the electrolytic decomposition of water, in which two volumes of hydrogen gas are produced for every one volume of oxygen; but you have seen it so often, and my time is expiring so quickly, that I think I had better go on telling my story. Let me now direct your attention to the oxygen compounds of sulphydric acid, as shown in the table:

H_2S	Sulphydric acid	Cl_2S
H_2SO	wanting	Cl_2SO
H_2SO_2	wanting	Cl_2SO_2
H_2SO_3	Sulphurous acid	
H_2SO_4	Sulphuric acid	

In this series we have two gaps, which, however, we can fill up by the chlorine representatives of the missing bodies Cl_2SO, and Cl_2SO_2 respectively, which are obtainable from Cl_2S by successive oxidation. The first product actually afforded by the oxidation of sulphydric acid is sulphurous acid. Thus, if we burn sulphuretted hydrogen in air or oxygen we obtain sulphurous acid. You observe the gas burns in this globe of oxygen with great brilliancy, and we have in the globe the product of its oxidation or combustion, namely, sulphurous acid, the presence of which is manifested to you by the deep blue colour produced on the addition of a solution of starch and iodic acid. Hence, if we add oxygen to sulphydric acid H_2S, we get sulphurous acid, H_2SO_3, and conversely, if we take away oxygen from sulphurous acid, by means of nascent hydrogen, for instance, we reobtain sulphydric acid. By a further oxidation the sulphurous acid H_2SO_3 becomes sulphuric acid H_2SO_4. Mere exposure to air is sufficient to effect the change, or we may use more powerful oxygenants. I can show you this conversion in a very simple manner. We have here a solution of sulphurous acid, and if we add to it a little chloride of barium we get no precipitate, because the sulphite of barium is moderately soluble in water. But if we now add some chlorine water we oxidate the sulphurous acid into sulphuric acid, and at once get a precipitate of sulphate of barium. Conversely, by deoxidising sulphuric acid we get sulphurous acid, as in the ordinary process for preparing sulphurous acid. Including our chlorine representatives of the two missing bodies, we have here a second series of acids, associated with one another by a common increment of composition and by mutual metamorphosis. Sulphuric acid H_2SO_4 is the representative on the sulphur series of perchloric acid $HClO_4$ on the chlorine series. Each contains one atom of the radicle which gives the special character to the acid, in the one case chlorine, in the other sulphur. Each contains also four atoms or volumes of oxygen; but whereas perchloric acid contains only one atom or volume of hydrogen, sulphuric acid contains two atoms or two volumes. And this difference in composition leads to a marked difference in the properties of the two acids. Perchloric acid $HClO_4$ has only one atom of hydrogen that can be replaced. Hence we have only one salt, such, for instance, as perchlorate of potassium, $KClO_4$, and only one ether, such, for instance, as perchloric ether $EtClO_4$. But sulphuric acid has two hydrogen atoms that can be replaced. Hence we have acid salts, neutral salts, double salts, acid ethers, neutral ethers, double ethers, and saline ethers, as shewn in the table.

H_2SO_4	Sulphuric acid.
$KHSO_4$	Acid sulphate of potassium.
K_2SO_4	Neutral sulphate of potassium.
$KNiSO_4$	Potassio-sulphate of nickel.
$EtHSO_4$	Ethylo-sulphuric acid.
Et_2SO_4	Neutral sulphate of ethyl.
$EtMeSO_4$	Ethylo-sulphate of methyl.
$EtKSO_4$	Ethylo-sulphate of potassium.

Now this property of forming acid and double salts, and acid and double ethers, &c. indicates a fundamental difference in character between sulphuric and perchloric acids, a difference that is satisfactorily represented by the difference in their formulæ as here written down, $HClO_4$, and H_2SO_4, a difference, however, which is not indicated in any English treatise on chemistry. The same bibasic character is manifested as decidedly by the sulphurous and sulphydric acids.

Now we will proceed with another gas, namely, phosphamine, which is a body also containing hydrogen, and if we make an iron wire red-hot in this gas we take away the phosphorus and leave the hydrogen. In this case the two volumes of phosphamine will give three volumes of hydrogen, or the quantity of gas will actually increase. The iron wire has taken up the phosphorus and the gas has expanded. We will bring the mercury to the same level in the two limbs of the tube and then you will perceive the actual expansion. In this case the two volumes of gas have increased to three. Two volumes of chlorhydric gas yield one volume of hydrogen; two volumes of sulphydric gas yield two volumes of hydrogen; and two volumes of phos-

phamine yield three volumes of hydrogen, and this is a most important distinction between the three classes of hydrides to which these three gases respectively belong.

Two volumes of each of the twelve gases shown in the table yield as many volumes of hydrogen as are indicated in their respective formulæ.

HF	Fluorhydric.	H_2O	Water.	H_3N	Ammonia.
HCl	Chlorhydric.	H_2S	Sulphydric.	H_3P	Phosphamine.
HBr	Bromhydric.	H_2Se	Selenhydric.	H_3As	Arsenamine.
HI	Iodhydric.	H_2T	Tellurhydric.	H_3Sb	Stibamine.

I may illustrate to you the constitution of this third class of hydrides by means of ammonia, which stands first on the list. I can show you the decomposition of ammonia in a different manner, by means of an instrument for which I am indebted to the kindness of Dr. Hofmann. I have in this U tube a quantity of ammoniacal gas, through which we are going to pass a succession of electric sparks. You will notice the small sparks taking place at the upper part of the tube. Now that small spark is decomposing the ammoniacal gas, and you see the bulk of gas is sensibly increasing. While the experiment is going on, we will proceed with our series of oxides of phosphamine.

H_3P	Phosphamine	Cl_3P	Et_3P.
H_3PO	wanting	Cl_3PO	Et_3PO.
H_3PO_2	Hypophosphorous acid.		
H_3PO_3	Phosphorous acid.		
H_3PO_4	Phosphoric acid.		

At starting we meet with a gap. In the first series there are no gaps, in the second series there are two gaps, and in the last series there is one gap, but in this case we have the chlorine representative of the missing body, and Mr. Brodie has ascertained that by directly oxidating this body, Cl_3P, he gets that body Cl_3PO. Or I may draw your attention to another representative of this missing compound, namely, the oxide of triethyl-phosphine. The liquid I have in my hand, which was discovered by Dr. Hofmann, through whose kindness I am enabled to show it you, is triethyl-phosphine, Et_3P, or phosphamine in which the three atoms of hydrogen are replaced by ethyl; and when this body is acted upon by oxygen it becomes converted into the ethyl representative of our missing body. I will here show you the experiment. I am about to fill this tube with oxygen; now into this tube of oxygen we are going to put a little triethyl-phosphine. On warming the two bodies a combination will take place, and we shall have produced the compound Et_3PO, that is the ethyl representative of our missing phosphorous body [explosion]. That noise was consequent upon the union of the oxygen in the tube with this ethyl representative of phosphuretted hydrogen or phosphamine.

Now I think our decomposition of ammonia by the Ruhmkorff spark has gone on to a sufficient extent. We will just reduce the mercury in the two limbs to the same level by letting out some of the mercury in this limb, and I think you will be able to see the expansion which the ammoniacal gas has undergone. You see the two volumes contained in the tube have become very nearly four volumes, and would have become quite four volumes if we had allowed the action to have gone on a little longer. All our compound gases occupy two volumes. Hence when we abstract the phosphorus from two volumes of phosphamine H_3P, we get three volumes of hydrogen left. When we decompose two volumes of ammonia H_3N by the electric spark, we convert them into three volumes of hydrogen and one volume of nitrogen, making altogether four volumes.

We now come to the first actual oxide of phosphamine, namely, hypophosphorous acid. This acid is not familiarly known to chemists, and its modes of formation have not been much studied. I do not know that it has ever been obtained by oxidating phosphamine, but I know the reverse instance, that you do get phosphamine by deoxidating hypophosphorous acid. I cannot say whether this body H_3PO_2, has been obtained from that H_3P, by adding oxygen to it, but I know that this body H_3P, is obtained from that H_3PO_2, by taking oxygen from it. When we act upon hypophosphorous acid, with nascent hydrogen, or when we heat the acid or any one of its salts we get phosphuretted hydrogen produced. We have here some of the hypophosphite of lime which is a salt a good deal used in medicine; when we heat this substance, it gives off phosphuretted hydrogen, which takes fire, as you perceive, and this is the only mineral salt I think I may say which is inflammable. It is a saline substance, looking like common salt, and the moment you heat it, it gives off phosphuretted hydrogen, and hence the mass burns very much in the same manner that phosphorus does. This brings me to the end of my hour, but not to anything like the end of what I intended to say, and you will perhaps kindly afford me a few minutes more to bring my subject to a conclusion. We have just said that hypophosphorous acid, by deoxidation, forms phosphuretted hydrogen; now by oxidation, it forms successively phosphorous and phosphoric acids, the two next bodies on our list. Phosphorous acid H_3PO_3 may be produced by the direct oxidation of phosphuretted hydrogen. Thus a mixture of phosphuretted hydrogen and oxygen, standing over water, is gradually absorbed with formation of phosphorous acid. Conversely, when phosphorous acid is acted upon by nascent hydrogen, its oxygen is abstracted, and it is reconverted into phosphuretted hydrogen. Phosphoric acid H_3PO_4 is producible by the oxidation of phosphuretted hydrogen, of hypo-phosphorous acid, and of phosphorous acid. It is a very stable substance, but nevertheless we are capable of taking away its oxygen and thereby liberating phosphuretted hydrogen, as is the case, for instance, when we act upon it by metallic sodium. Here again then we have a series of naturally associated and mutually convertible bodies, represented by the simplest possible formulæ, by formulæ which do not express any speculative view whatever, but merely indicate the indisputable fact that these bodies, or their representatives, differ from one another in composition, by the successive increments of one, two, three, and four oxygen atoms. Phosphoric acid, H_3PO_4, is the representative on the phosphorus series, of sulphuric acid H_2SO_4, on the sulphur series, and of perchloric acid $HClO_4$, on the chlorine series; but whereas perchloric acid contains only one atom of hydrogen and can form only one class of salts and ethers; whereas sulphuric acid contains two atoms of hydrogen and can form only two classes of salts and ethers; phosphoric acid contains three atoms of hydrogen, and can form three classes of salts and ethers. One-third, two-thirds, or three-thirds of its hydrogen may be displaced by a metal or basic radicle, or the hydrogen may be partly or wholly displaced by two or three different metals, or by two or three different radicles, or by a mixture of metals and radicles, thus: $EtKCuPO_4$, or $H.NH_4NaPO_4$, &c.

We must now pass on to another primary hydride, namely, that of silicon, the siliciuretted hydrogen of Wöhler. The composition of this body has not been ascertained. It has been ascertained, however, that the substance from which it is obtained by the action of chlorhydric acid, is a silicide of magnesium, represented by the formula Mg_4Si, whence we infer the formula of siliciuretted hydrogen to be H_4Si, analogous to that of marsh gas H_4C, a conclusion strongly confirmed by the composition of chloride of silicon, which has been demonstrated to be Cl_4Si, that is, a chloro-representative of siliciuretted hydrogen. Each of our other primary hydrides has yielded us a remarkably stable acid, formed by the addition of four atoms of oxygen to the hydride; and our hydride of silicon ought to behave in the same manner, thus:

Chlorhydric acid	H Cl	$HClO_4$	Perchloric acid.
Sulphydric acid	H_2S	H_2SO_4	Sulphuric acid.
Phosphamine	H_3P	H_3PO_4	Phosphoric acid.
Hydride of Silicon	H_4Si	H_4SiO_4	Silicic acid.

Now whether or not H_4SiO_4 is the correct formula for silicic acid, it is quite certain that the great majority of

simple and well-defined silicates may be referred to that type, as illustrated in the table.

Orthosilicates.

Et_4SiO_4	Silicic ether.	Gl_4SiO_4	Phenakite.
Li_4SiO_4	Silicate of lithium.	Ce_4SiO_4	Cerite.
$Na_2H_2SiO_4$	Silicate of sodium.	Fe_4SiO_4	Fayelite.
Ca_4SiO_4	Silicate of calcium.	$Fe_3Mn_2SiO_4$	Knebelite.
Mg_4SiO_4	Olivine, Chrysolite.	$Cu_2H_2SiO_4$	Dioptase.
$Ca_3Mg_2SiO_4$	Batrachite.	Al_2CaSiO_4	Anorthite.
Zn_4SiO_4	Zinc glance.	Al_2MnSiO_4	Karpholite.

This next table illustrates to you the general relations of the perchloric salts and ethers, to their sulphuric, phosphoric, and silicic analogues. The existence of the silicated compounds corresponding to the formulæ in italics, has not yet been established.

Acids, Salts, and Ethers.

H Cl	$H ClO_4$	$\begin{cases} Na\ ClO_4 \\ Et\ ClO_4 \end{cases}$		
H_2S	$H_2S\ O_4$	$\begin{cases} Na_2S\ O_4 \\ Et_2S\ O_4 \end{cases}$	$Na\ H\ S\ O_4$ $Et\ H\ S\ O_4$	
H_3P	$H_3P\ O_4$	$\begin{cases} Na_3P\ O_4 \\ Et_3P\ O_4 \end{cases}$	$Na_2H\ P\ O_4$ $Et_2H\ P\ O_4$	$NaH_2P\ O_4$ $Et\ H_2P\ O_4$
H_4Si	H_4SiO_4	$\begin{cases} Na_4Si\ O_4 \\ Et_4Si\ O_4 \end{cases}$	$Na_2H\ Si\ O_4$ $Et_2H\ Si\ O_4$	$Na_2H_2SiO_4$ $Et_2H_2SiO_4$ | NaH_3SiO_4 EtH_3SiO_4

Considering the relations of ammonia and phosphuretted hydrogen, H_3N and H_3P respectively, and the relations of marsh gas, and siliciuretted hydrogen, H_4C and H_4Si respectively, we should expect to have nitrates and carbonates having the general formulæ M_3NO_4, and M_4CO_4 respectively, corresponding to ordinary phosphates and silicates having the general formulæ M_3PO_4 and $M_4Si\ O_4$ respectively. It is observable, however, that in addition to our ordinary phosphates and silicates, we have other phosphates and silicates, known respectively as metaphosphates and metasilicates, which differ from the ordinary salts and the loss of an atom of base, and that it is these metasalts to which our ordinary nitrates and carbonates correspond, thus:—

Phosphate	$M_3PO_4 - M_2O = MPO_3$		Metaphosphate.
		MNO_5	Nitrate.
Silicate	$M_4SiO_4 - M_2O = M_2SiO_5$		Metasilicate
		M_2CO_3	Carbonate.

We are acquainted, however, with a considerable number of carbonates and nitrates, which we may call orthocarbonates and orthonitrates respectively, that do correspond in their formulæ with our ordinary silicates and phosphates, as shown in the table.

Orthocarbonates.

Ca_4CO_4	Dicarbonate of calcium
Zn_4CO_4	Dicarbonate of zinc
Mg_3HCO_4	Dicarbonate of magnesium
Pb_4CO_4	Dicarbonate of lead
Pb_3HCO_4	White lead
Cu_4CO_4	Mysorine
Cu_3HCO_4	Azurite
$Bi'''HCO_4$	Dicarbonate of bismuth

Orthonitrates.

Pb_2HNO_4, $Pb_3\ NO_4$	of lead
$Hg_3\ NO_4$, Hg_2HNO_4	of mercury
$Bi'''NO_4$	of bismuth

The succeeding tables present you with lists of the principal ter-oxy and tetra-oxy mineral acids.

Ter. Ox. Acids.		*Tetra Ox. Acid.*	
Chloric	$H\ Cl\ O_3$	Perchloric	$H\ Cl\ O_4$
Bromic	$H\ BrO_3$	Periodic	$H\ I\ O_4$
Iodic	$H\ I\ O_3$	Permanganic	$H\ Mn_2O_4$
Nitric	$H\ N\ O_3$	Sulphuric	$H_2S\ O_4$
Metaphosphoric	$H\ P\ O_3$	Selenic	$H_2Se\ O_4$
Sulphurous	$H_2S\ O_3$	Telluric	$H_2T\ O_4$
Selenious	H_2SeO_3	Oxalic	$H_2C_2\ O_4$
Tellurous	$H_2T\ O_3$	Molybdic	$H_2Mo_2O_4$
Carbonic	$H_2C\ O_3$	Vanadic	$H_2V_2\ O_4$
Metasilicic	H_2SiO_3	Tungstic	$H_2W_2\ O_4$
Titanic	$H_2Ti\ O_3$	Chromic	$H_2Cr_2\ O_4$
Stannic	$H_2Sn\ O_3$	Manganic	$H_2Mn_2O_4$
Vanadous	$H_2V_2\ O_3$	Ferric	$H_2Fe_2\ O_4$
Phosphorous	$H_3P\ O_3$	Orthonitric	$H_3N\ O_4$
Arsenious	$H_3As\ O_3$	Phosphoric	$H_3P\ O_4$
Antimonous	$H_3Sb\ O_3$	Arsenic	$H_3As\ O_4$
Bismithous	$H_3Bi\ O_3$	Antimonic	$H_3Sb\ O_4$
Boracic	$H_3B\ O_3$	Orthocarbonic	$H_4C\ O_4$
Aluminous	$H_3Al_2O_3$	Silicic	$H_4Si\ O_4$

Hence it seems we may take as our general type for an acid the formula $H_xR_yO_z$, where H_x represents the atoms of hydrogen, which, save in carbon compounds, are found to vary only from 1 to 4; where R_y represents the acid radicle, that is the chlorine, or sulphur, or phosphorus, or carbon, &c. which gives the special character to the acid, and which, save in carbon compounds, is usually confined to 1 or 2 elementary atoms; and where O_z represents the atoms of oxygen which generally range from 0 to 4, but occasionally extend to higher numbers.

I did intend to make a few remarks on the hydration of salts, but time will not allow me. I will, however, direct your attention to a remarkable experiment which I am able to show you through the kindness of Mr. Hadow of King's College. This bright red sheet of paper owes its colour to a deposit upon its surface of the hydrated platino-cyanide of magnesium. Now when we heat this paper over a lamp, the red platino-cyanide loses water and becomes pale yellow, or nearly colourless, as you perceive. If we now moisten the portion of the paper bleached by the heat, we restore the red colour, but if we moisten the unheated portion of the paper which is still red, we cause the redness to disappear. The solution of platino-cyanide of magnesium is colourless, hence the bleaching effected by water; the ordinary hydrated salt is red; and the less hydrated salt is pale yellow, hence the bleaching effected by heat, and the restoration of the red subsequently effected by moisture. It now only remains for me to say, in conclusion, that if chemists will be content to associate bodies without any speculative views of their constitution, by means of unitary formulæ arranged in series, they will gain one of the most easy methods of correlating different bodies, a method which is true because it involves nothing but the fact of their relation of composition, and their relation of properties, exemplified in the case of the acids by mutual metamorphosis. On the first occasion on which I had the honour of addressing this audience, I caused some merriment by criticising the formulæ of others. It was then suggested to me that instead of criticising bad formulæ I should introduce better ones. Those then are my seriated substitution-formulæ, which if they do not express the whole truth at any rate express no falsehood.

SOCIETY OF ARTS, *Wednesday, 28 March* 1860.

THOMSON HANKEY, *Esq., M.P. in the Chair.*

THE paper read at this meeting of the Society of Arts, by Mr. ROBERT BARCLAY, was devoted to the consideration of various means for the *Prevention of Forgery arising from the Alteration and Falsification of Cheques, Notes, &c.* The lecturer first pointed out the liability to fade to which ordinary writing ink is subject, and the great difficulty of obtaining a carbon-ink of the necessary consistence and which cannot be washed from the surface of the paper. An ink composed of sugar, indigo, and dilute sulphuric acid may give very permanent characters, but a hot iron must be passed over the writing to effect the carbonisation of the sugar, and the acid thus concentrated may exhibit its destructive powers in an unpleasant manner upon the substance of the paper itself. Mr. Barclay then turned to the question of the fraudulent alteration of commercial documents, &c. by chemical means, and of the importance of preventing this with the aid of the same science. "I therefore propose to consider," he said, "in the first place, the various expedients which have been proposed and carried out into practice for the prevention

of this description of forgery, several instances of which have occurred (one as lately as the spring of 1859, at one of the branches of the Bank of England), in which both the crossing was obliterated and the amount altered. This is a danger already in a measure provided against by the public, and I shall endeavour to show that the expedients hitherto adopted with this view are imperfect, and that a complete scientific defence against the skilful chemical abstraction of writing is required and provided by the chemically prepared white writing paper which I am desirous to introduce to the notice of your Society and the public.

"In the second place, I shall show that, by the incorporation of similar chemical substances in ordinary writing papers, we may so remove the fading tendency of common writing ink as to render it permanent to a great age. I shall also describe a method of rendering printed characters unalterable by any process whatever, and effectually preventing the mechanical erasure of writing. Before describing the remedies which have been proposed by others, it may be well to exhibit the wide range of substances which more or less perfectly obliterate writing ink, under the three following heads:—

Bleaching Agents.	Acids and Acidulous Salts.	Alkalies.
Chlorinated carbonate soda	Binoxalate-potass	Potash
Solution of bromine	Hydrochloric acid	Soda
Ditto chloride of ditto	Nitro muriatic acid	
Chloride of lime	Oxalic acid	
Bromide of lime	Citric and tartaric acid	
Solution of chlorine	Sulphurous and	
Chromic acid	Sulphuric acid	
Oxygenated water		

"I have often remarked that, even amongst persons possessing some knowledge of chemistry, an impression prevails that acids are the most ready and powerful dischargers of ink. The fact, however, is, that bleaching liquids are vastly more effective, and their action is more elegant and perfect. Hence has resulted the erroneous conclusion that the obliteration or discharge of ink is a hazardous and doubtful process, and that, therefore, any special means of prevention are not imperatively demanded.

"We have here a list of 18 substances of the most diverse chemical properties, and it will be seen that the problem to be solved is one of considerable difficulty, because, if there is a single reagent on the list which will discharge and bleach writing ink, a method possessing, perhaps, the highest excellence in absolutely preventing the discharge of ink with one class of substances, is totally useless if attacked with another of an opposite class."

Various patents, having for their object the production of a paper calculated to render abortive all attempts to obliterate any portion of the writing upon its surface, were then cited. We will briefly glance over the list. The process of Gabriel Tigere, patented in 1817, consisted in impregnating the paper with prussiate of potassa before sizing it, which latter operation was then performed as usual. In 1822, William Robson's method of preventing frauds upon cheques, bills of exchange, &c. was patented; here, vegetable colours, those extracted from saffron and logwood being preferred, were ruled or printed upon the paper in such a way, that upon the application of any acid these colours would be destroyed as well as the ink. The cheque paper now in use may be said to be in some measure based upon this patent, as they are nearly always tinted with various organic colouring matters. W. Stone's patent, in 1851, was for the use of ferrocyanide of potassium, iodide of potassium, and starch, which substances were applied to the paper during the sizing process. Very similar to that of Tigere is the process of W. Herapath, patented in 1858, who however employs, in addition, the ferri- and sulpho-cyanides of potassium. Robson's method is decidedly unsafe, inasmuch as the writing may be readily discharged at any part, and the colour or engraved work may be afterwards retinted wherever necessary. The process of Tigere is, according to Mr. Barclay, based upon sounder principles, as upon attempting to discharge the writing with any acid or acidulous salts, Prussian blue is instantly formed, and the writing is thus made still more apparent. The ferrocyanide constituting the sole security of this paper, may however be quickly dissolved out with water first made slightly alkaline. This paper also offers no protection against bleaching agents.

For a description of his own process, we will take Mr. Barclay's words *verbatim*:—

"The constituent of my patent is the incorporation of an insoluble ferrocyanide and an insoluble salt of manganese with the paper pulp. I have found the insoluble white ferrocyanide of manganese, in a state of purity, the most suitable for my purpose. A special process is adopted for preventing waste and fixing the insoluble powder in the fibre of the paper, and the discoloration during the sizing process is prevented by the use of a mordant of the acetate of alumina, which perfectly fixes the size and prevents its decomposition; the paper is passed through the drying process with rapidity, and in this way the practical difficulties in the incorporation of a ferrocyanide are completely surrounded, and I obtain a pure white paper which effectually obviates the objection to the use of tinted papers, and renders no change whatever in the appearance of paper to which the patent is applied.

"This is a most important practical result, as any peculiarity of appearance involving a change is inconvenient, and is resisted both on valid practical grounds, and also on the simple principle of conservation, still I wish it to be clearly understood that, under my patent, any description or tint of paper can be produced.

"The chemical principle of this paper is perfectly adapted to obviate the dangers arising from the wide range of ink discharging chemical substances.

"By the application of acids the writing ink becomes fixed more firmly in the paper, and is converted into Prussian blue. Mordanted with the alumina contained in the size, chlorine and bromine have a still more powerful effect in causing the writing instantly to penetrate to the back of the paper, and to assume greater intensity than before, and the stains of the peroxide of manganese also appear. Chloride of lime and chlorinated soda, and bromine of lime, produce the intense brown dye of the peroxide of manganese, as calico printers term it, manganese brown; if this is dissolved out it will be found the writing will reappear, being not destroyed but merely obscured.

"Alkalis and their carbonates, and oxygenate water, have a similar effect in producing manganese brown. Chronic acid causes the deposition of the green oxide of chronium in addition to the manganese brown.

"Every chemical substance which discharges the colour of Prussian blue produces manganese brown, and *vice versâ*. The chemist, therefore, is involved in an alternation of effects whichever class of chemicals is applied, and in the present state of our knowledge it is a net from whose meshes the utmost skill will not extricate him. As long as the insoluble material remains in the paper the writing cannot be destroyed. By dissolving out, and destroying the protective material from the substance of the paper, which in itself is a most hazardous operation, we may discharge a portion of the ink, but this involves still greater difficulties, since, when done, it is found to be totally inapplicable, as the stain, alternating according to the chemicals used, drives the operator to the edge of the document, and every portion of it is destroyed. Professor Brande, of the Mint; Dr. Miller, of King's College, and Mr. R. Warington, of Apothecaries' Hall, will bear me out in saying that actual experiment will alone enable any person to appreciate the vast difficulties which present themselves in the effort to discharge a portion of the writing. These, though they employed time, patience, and the resources of their well-known skill and ingenuity, they failed to overcome.

"I have myself most fully followed up, by actual experiment, every idea, for evading the security of the paper,

which has been suggested to me by scientific friends, and though some hundreds of experiments have been made with this view, I have not yet seen a single successful attempt to discharge a portion of writing placed upon this paper, without the production of stains or the destruction of the entire document.

"These stains entirely prevent the possibility of restoring, by artistic skill, the appearance of a cheque or other document printed or written on this paper.

"I produce specimens of the paper containing various amounts of the protective material."

Further on he says:—

"The cheques of the London bankers may be thus classified:—

"1. Tinted cheques which are of imperfect security, and can be evaded without the process of re-tinting.

"2. Tinted cheques exhibiting the perfection of Robson's principle, but which are evaded by bleaching the writing and restoring the tinting.

"3. Cheques on Tigere's patent, evaded by bleaching liquids, and slightly re-tinted.

"4. Cheques on plain paper, which present little difficulty to any and every alteration which the convenience of a forger may require.

"All these checks are, however, open to a variety of manipulations, and I would call attention to the ease with which the writing may be bleached in the lines of the letters or figures, and the most elaborate, and at first sight, inimitable engraving may be re-produced by joining the lines of the engraved ground-work. It is in many cases necessary only to alter a very few letters to increase the amount of a cheque, but a larger portion of these engraved tablets may be reproduced by an artist's hand with certainty, it is merely a question of a little more time and labour.

"Vegetable tinted paper may be re-tinted by a person accustomed to water-colour painting.

"I consider the principle of obliging the forger to discharge in addition to the ink a vegetable colour, imperfect and founded on a false assumption, viz. that a colour which is bleached cannot be re-tinted. The reply to those who urge the difficulty of doing it, is simply that there is no occasion to destroy more than a very small portion of the tinting, and that this is not a question for a chemist but for an artist, and also that any person who is not an artist, if he will take the pains, may prove to himself that it is not a matter requiring much skill.

"The principle of my paper is to oblige the forger permanently to dye a white paper, by an attempt to bleach the ink.

"The difficulty of discharging the smallest portion of writing upon cheques printed on my peper, is precisely as great as if the largest portion is operated upon."

We omit some observations upon the general importance of the subject, but of no special interest, and also a mass of somewhat irrelevant matter intended to evidence the great durability of Prussian blue, *except* when exposed to the action of alkalies, or to that of moisture and sunlight combined. Our author, however, seems not to be aware that this pigment may, by careful manipulation, be dissolved in oxalic acid. We learn from a quotation from Stahl, that Prussian blue was accidentally discovered in 1704, in the following manner:—

"A colour maker, of the name of Diesbach, who was making a cochineal lake called Florentine lake, mixed the decoction of cochineal with alum and a little sulphate of iron. The colour he struck with an alkali, and being once short of it, he was given by Dipple, a chemist, in whose laboratory he was working, salt of tartar, with which this chemist had distilled many times — an animal oil. The lake, which by the usual alkali would have been thrown down a red, became first purple, then blueish, then a most beautiful blue or gentian colour.

"Diesbach was aware of the way in which the salt of tartar had been previously treated.

"Dipple, to whom he communicated the intelligence of this strange appearance, knew at once it must proceed from the peculiarity of this salt of tartar he had given him, and investigated the result, and he was soon able to give this quality in a simple manner to another salt. These researches were attended with happy results, and from this time forward the discovery of Prussian blue was established.

"This blue was first shown in the Exhibition of the Academy of Berlin, in the year 1710, without any description of the proceeding by which it could be manufactured. Many chemists endeavoured to discover the secret.

"In the year 1724, Mr. Woodward, F.R.S., published the process in the *Philosophical Transactions*."

Mr. Barclay claimed the use, not only of the ferrocyanide of manganese, but also the combinations of zinc, lead, tin, and copper, with the radical just indicated. Upon the conclusion of the paper, an animated discussion supervened, of which we can only notice the more prominent points.

Mr. Herapath (of Bristol) thought that as Mr. Barclay had closely criticised other patents, he should have mentioned that of David Stevenson, 1837, No. 7313. This patent was for exactly the same thing as Mr. Barclay's, viz. the use of ferrocyanide of manganese, and had expired in 1851. As Stevenson's process had fallen into disuse, it might fairly be presumed that Mr. Barclay's, which was identical with it, was also valueless.

Mr. H. N. Nissen had come prepared to exhibit to the meeting specimens of Mr. Barclay's paper from which the ink had been completely extracted in two or three minutes, and in most cases without leaving any stain.

Mr. Coe differed with Mr. Barclay on several points, considering that he had considerably overrated the dangers to which notes, cheques, &c. were subject. The experience of the Bank of England relative to altered cheques was so small, that they could hardly remember a case in which a cheque had been tampered with by chemical means, and with Glyn's and the London and Westminster banks it was precisely the same. The Bank of England employed only a plain white cheque, which appeared to give all needful security. The great majority of frauds were effected by forgery, on blank cheques improperly obtained. His own experiments had shown that the writing could be completely obliterated from Mr. Barclay's paper.

Mr. Fox pointed out that in the specimens shown by Mr. Nissen the writing had not been obliterated without making a palpable alteration on the surface of the paper.

Dr. Miller could corroborate all Mr. Barclay's statement: he had never succeeded in extracting the ink so completely as in those specimens exhibited by Mr. Nissen.

Mr. Barclay said that Mr. Herapath had failed to establish the identity of Stevenson's patent and his own. The specimens produced by Mr. Nissen, where the writing had been extracted, would be immediately detected by any bank clerk. The writing itself was not in a firm hand, and the ink had never penetrated the paper. Various proportions of protective material could be introduced into the paper, and Mr. Nissen's specimens had not been strongly prepared.

The Chairman in proposing that the thanks of the Meeting be awarded to Mr. Barclay, said that even those who objected to some of his views must admit that a free discussion like the present must tend to good. At the conclusion of his remarks the vote of thanks was passed, and the Meeting separated.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, 20 March 1860.

Wm. Fairbairn, *Esq., F.R.S. &c. President, in the Chair.*

The President exhibited two large pans of cast iron, procured by Mr. Worthington from China, where they are used for boiling rice. The metal, which was at the strongest part only one-tenth of an inch in thickness, possessed con-

siderable malleability. The President remarked that the art of making such large castings of thin metal was unknown in England.

Some conversation took place respecting the proposed Telegraph to connect Great Britain with America, by using Iceland, Greenland, and Labrador as intermediate stations.

Mr. F. Gisborne, the original projector of the Atlantic Telegraph, said that the fears which had been expressed that the cable would be destroyed on the coast of Labrador by grounded icebergs, were not warranted. He was intimately acquainted with the locality, and although there was an immense number of icebergs which grounded on the coast, some, as he had himself observed, in seventy fathoms water, yet, as at Newfoundland, there were inlets with water in the middle of sufficient depth to secure the cable from injury.

A paper was read by John Graham, Esq. entitled *On the History of Invention as applied to the Dyeing and Printing of Fabrics. Part II. Mechanics.*

Professor Roscoe made a communication to the Society concerning the alleged practice of arsenic eating in Styria. He stated that his object was to settle the long debated question as to the possibility of the human body being able to accustom itself to doses of arsenic, as it is known to be able to do to doses of opium, alcohol, and other substances taken in quantities, which under ordinary circumstances would produce fatal effects. The statement that the peasants of Styria are in the habit of taking doses of arsenic which would to ordinary persons prove fatal, seems to originate with Von Tschudi. Professor Taylor in his work on Poisons, places discredit on Von Tschudi's statements, but gives no positive proof concerning the matter. Dr. Roscoe had obtained much information on the subject direct from Styria, through his friend Professor Von Pebal of Lemberg, and the subject was now mentioned simply to call the attention of the members of the society to the question, and, if possible, to obtain further definite information. Dr. Roscoe did not venture to express any opinion on the subject at present; he hoped before long to receive conclusive evidence from a circular addressed to the medical men of Styria; the results of the inquiry he would communicate on a future occasion. Mr. John Graham remarked that much information on the effects of small and continued doses of arsenic might probably be gained in Manchester, where arsenical preparations were used in so many different manufactures. Dr. Roscoe stated that he should feel much obliged if the members could give him opportunity of examining any case of the action of arsenic upon the human body.

Microscopical Section.—*March 19th*, 1860.

A communication was read from Mr. John Hepworth, of Crofts Bank, accompanying a box of mounted specimens of various kinds of cotton and other fibrous materials.

Mr. Hepworth states that "the average breadth of the cotton cell is about $\frac{1}{500}$th of an inch, except near its attachment, where it gradually tapers to about $\frac{1}{700}$th of an inch.

"The ultimate fibre of which the cell wall is composed is longitudinal, and inclined in a spiral direction round the tube (? this might arise from position); it is rarely seen, and never, Mr. Hepworth thinks, except with polarised light and good definition. The cell wall in most specimens appears homogeneous."

Mr. Dancer presented a bottle of water from his marine aquarium, containing large rotifers and other marine infusoria.

Mr. Brittain exhibited a specimen of a new mode of mounting large objects in Canada Balsam.

Mr. Brothers showed the circulation in an acharis, spawn of snails, infusoria, &c.

Mr. Mosley exhibited some living marine animalculæ from the fosse or inundation at Gibraltar, consisting of gammarus fluviatilis, temora, and others, collected by Mr. Frembly, of that place.

Chemical Society.—The next meeting of this Society will take place on Thursday, 19th April, when the following papers will be read:—*Contributions to the History of Cinnamic Acid*, by Mr. D. Howard; *On Crystallised Potassium*, by Mr. C. E. Long. Our report of the last meeting of this Society is, owing to the length to which Dr. Andrewes' paper *On Ozone* extends, postponed until the next number of the Chemical News.

NOTICES OF PATENTS.

For the Manufacture of a Pulp for Paper-making and other purposes, from the leaves or fruit of the citron, orange, or lemon tree. Frederick Brown. (Provisional protection only.)

The patentee takes the leaves or fruit and steeps them in boiling water for half an hour. The mass is then put in the engine and washed with hot water; then clean lime water is added and the washing proceeded with, and when finished the mass is pulped with weak alkali dissolved in hot water. He then bleaches with chloride of lime.

As long as there are a multitude of substances from which cheap paper can be made, we are at a loss to see the advantage of using even the leaves of the trees alluded to. As for the fruit, we can only say that to turn good oranges, lemons, or citrons into middling or bad paper would probably lead to the punishment such a vile metamorphosis would deserve.

Improvements in treating Poppies to obtain a Product resembling Opium therefrom. William M'Andrew and Charles Wilson Boyd. (This process received provisional protection only.)

The patentees, instead of making incisions in the poppy, gather and dry the plant and make an alcoholic extract. It is this extract which they consider to resemble opium. How far the resemblance goes they do not say, and it is plain that for any substance to replace a drug of such vast importance as opium, its chemical composition and medicinal properties would have to undergo the most searching investigation.

A new Moveable Stopper for Gaseous Liquids. P. A. A. Trouttet of Dijon. (Provisional protection only.)

An ingenious contrivance, capable of being adapted to any bottle. By its use any quantity of a gas-impregnated fluid can be obtained without wasting the remainder. It would require an engraving to enable it to be described clearly.

Improvements in Extracting Oils from Coal and other minerals. Fred. Collier Bakewell. (American communication.)

The literature of the coal oil patents is a formidable subject to "get up." There are endless so-called "improvements," "discoveries," "adaptations," &c. There is, however, a wearying sameness about most of them. The present patent is not wholly free from this censure, for it consists mainly of rotating the retort while the coals are distilling. But, inasmuch as the machinery devised for the purpose appears to be simple and effective, and as the patentee uses a low temperature at the same time that he rotates his retorts, we think it probable that the process may be advantageous in regard to the quality and quantity of the oils yielded. The patentee insists upon the temperature not exceeding 850° F. Now in the ordinary retorts, in order to bring the coals in the centre to 850° it is absolutely necessary to raise the sides to a very much higher temperature than this, consequently there is great loss owing to the amount of gas produced. But by rotating the retorts it will be possible to keep the temperature much lower than would be practicable in any other way, because every part of the charge is brought in succession against the sides. The economy of the process is the question. Will the increase of produce pay for the wear and tear and interest of capital on the machinery?

CORRESPONDENCE.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

Colouring Matters obtained with Protochloride of Tin.—M. Scheurer-Kestner has communicated some new facts on the products of the oxidation of protochloride of tin, and the solution of some oxides in the bichloride. The bichloride of tin is prepared by oxidising, by means of nitric acid or chlorate of potash, the protochloride added to an equivalent of hydrochloric acid: but the product obtained is not pure. In oxidising the protochloride of tin by means of nitric acid without the addition of hydrochloric acid, the products obtained vary according to the concentration of the solutions. With very concentrated solutions there is a simple oxidation; but with dilute solutions one or more equivalents of nitric acid are fixed. The liquids obtained with concentrated solutions deposit crystals of the bichloride; the liquid separated from the crystals contains stannic acid in solution in the bichloride. The protoxide of tin is easily dissolved by the bichloride forming protochloride and stannic acid which remains dissolved in the excess of bichloride. By adding to the bichloride an excess of protoxide the liquid is changed to a moist mass. The solution filtered away is found to contain only the protochloride; and the paste left on the filter is composed of stannic acid. By oxidising the protochloride of tin with chromic acid a thick liquid of a beautiful emerald green colour is obtained. With titanic acid M. Jourdain has obtained red liquids.[1]

II. ORGANIC CHEMISTRY.

The Green Colouring Matter of Leaves. — M. Frémy has also studied the constitution and composition of chorophyll,[2] which he supposes to be made up of two colouring matters, a blue and yellow, the first of which he names *phyllocyanine*, and the second *phylloxanthine*. M. Frémy discovered that by the action of some bases the green matter of leaves is changed to a beautiful yellow substance, which is easily dissolved by alcohol. In this solution hydrochloric and some other acids will immediately restore the primitive green colour. To separate the blue and yellow matters, M. Frémy proceeded as follows:—He first placed in a stoppered bottle two parts of ether and one part of hydrochloric acid, diluted with a little water, and then shook the bottle strongly for some time. He then submitted to the action of this liquid the body produced by the decolorisation of the chlorophyll, shaking them together for some seconds. The effect was very remarkable. The ether dissolved the yellow matter of the leaves, and became of a beautiful yellow colour, while the hydrochloric acid reacted upon the green matter which had been decolorised, and produced a magnificent blue. The two colours are thus isolated, and, being retained by two different liquids, cannot be mixed to reproduce the green; but if the liquids are separated, and the colouring matters withdrawn from them, solution in alcohol, which dissolves both, gives immediately a green tint, comparable to that of the original chlorophyll. M. Frémy entertains some reasonable doubts whether his phyllocyanine and phylloxanthine really exist in vegetables, and proposes to continue and extend his investigations on the subject. The whole paper is very interesting, and deserves a longer notice than we can give in this correspondence.

Vegetable Colouring Matters.—M. Filhol has been engaged in the examination of vegetable colouring matters, and has discovered some facts which he now publishes as briefly as possible[3], intending to give all the details in a longer memoir. There exists in nearly all flowers, says M. Filhol, a substance which is scarcely coloured when in solution in acid liquids, but which becomes of a beautiful yellow colour when acted on by alkalies. This substance has the following properties. It is solid and of a slightly greenish-yellow colour. It is uncrystallisable, soluble in water, alcohol and ether, and not volatile. When moistened with strong hydrochloric acid it takes a bright yellow tint which immediately disappears when the mixture is diluted with water, leaving an almost colourless solution to which alkalies communicate a yellow colour. The matter is found in the green parts of plants as well as the flowers, and is no doubt the yellow dye found in the leaves of various plants. M. Filhol adopts the name given to it by Hope, and calls it *Xanthogene*. Mosses, he says, do not contain it, or at most, only a trace. It is also absent from some flowers, among others the *Pelargonium Zonale*, and *inquinans Papaver rheas*, Camellias and Salvias. These flowers under the influence of alkalies become blue or violet without the least mixture of green. The colouring matter of these flowers is much less alterable under the influence of air and alkalies than that of most other flowers.

Chemists who have examined yellow flowers, have proved that they owe their colour to several immediate principles; among others, *xanthine* and *xantheine*. The author has discovered *xanthine* in fruits as well as flowers.

III. TECHNICAL CHEMISTRY.

Chrome Green.—M. Casoria[4] gives the following process as the best and cheapest for obtaining chrome green of the first quality:—Mix one part of red chromate of potash with three of boracic acid, and reduce them to fine powder. Fuse the powder in a platinum capsule at a temperature a little below redness, and keep it in a state of fusion until the capsule appears lined with a beautiful green. Then remove the capsule from the fire and immerse it in a quantity of boiling water, stirring up the mass with a small stick. Throw on a filter the substance which is precipitated after the first washing, and continue to wash until the water runs away colourless. An emerald green precipitate of the greatest beauty will be left, which may be dried and pulverised.

MISCELLANEOUS.

New sort of Gun Cotton.—Recently prepared gun cotton soaked for a quarter of an hour in a saturated solution of chlorate of potash, and then pressed and carefully dried is said to have as strong an explosive power as fulminating silver.—*American Journal of Pharmacy.*

The Adulteration of Food Bill has passed the Lower House, and is now in consideration in the Lords. We must defer some remarks on the subject of the bill until our next number.

ANSWERS TO CORRESPONDENTS.

*** In publishing letters from our correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

W. G. — If our correspondent will repeat his queries they shall be attended to.

E. E. W. — Hopkin and Williams, manufacturing chemists, 5 New Cavendish Street.

Jas. Brown.—Will be answered in a future number.

J. M.—Consult a surgeon. We cannot under any circumstances give advice.

Jean Oyston.—Ultramarine blues are of two kinds, one in which the colouring matter is cobalt, and the other the artificial ultramarine which, according to Brunner, is prepared by repeatedly igniting a mixture of sulphuret of sodium and porcelain clay with fresh quantities of sulphur until the desired tint is produced.

Index.—We will look for the information this correspondent wants.

Chemicus is referred to Dr. Odling's Lecture for the explanation he seeks.

G. E. F.—The ignition was not carried sufficiently far.

THE CHEMICAL NEWS.

Vol. I. No. 20. — April 21, 1860.

THE ADULTERATION OF FOOD BILL.

In a recent number we gave an analysis of the bill introduced into the House of Commons by Mr. Scholefield and others for preventing the adulteration of articles of food or drink. In the course of its passage through the House some amendments have been introduced, and its action has been extended to Scotland and Ireland; but these amendments do not materially alter it. The great objection to the bill which we pointed out still exists, that is to say, the vendor of the adulterated article must be proved to have a knowledge of the adulteration: now a moment's thought must convince any body of the difficulty, nay, the impossibility even, in some cases of proving a guilty knowledge of this fact. Then, again, the bill permits the vendor to adulterate his goods to any extent with substances not injurious to health, provided he is careful not to warrant them genuine: thus he may add potato starch to his Bermuda arrowroot, and sell it at the price of genuine Bermuda without risk of prosecution so long as he does not insist on its genuineness, if a question whether it be so should happen to be put to him. The first consequence of the bill will therefore be to make this evasion of a positive affirmation of the purity of an article universal among tradesmen. It seems evident, in fact, that adulterations may be carried on within certain limits with perfect impunity: our tea may still contain leaves which have previously done duty; our pepper may contain flour; our milk, water; our beer, salt and treacle; and our butter, water, lard, and flour. All these and similar adulterations, be it remembered, being allowed provided the vendor does not warrant the articles he sells as being pure. Then with regard to other adulterations, such as alum in bread, and sulphuric acid in gin and vinegar, there would be no difficulty in finding chemists who would conscientiously declare that such admixtures were not injurious to health, so that magistrates would be placed in the difficult position of having to decide between scientific opinions diametrically opposed to each other, and whatever decision was given it would in all probability be appealed against.

We believe, therefore, that the bill as it stands will be found wholly ineffectual in checking the practice of adulteration. We can hardly conceive the possibility of a conviction taking place under it if the prosecutor is bound to prove both a guilty knowledge of the adulteration and that the adulterating matters are injurious to health. Nor do we see the necessity for his doing so; the tradesman who sells an adulterated article should be considered as a cheat and punished accordingly.

It is possible that cases might arise in which a slight fine would be adequate to the offence; but cases of this kind might safely be left to the discrimination of the justices; and most certainly we would not admit as an extenuating circumstance that the adulteration was made by the wholesale dealer. The provision we would suggest for a case where the tradesman had been the victim of the wholesale dealer would be to give the former the power of recovering the fine levied upon him from the real offender in the County Court. The fear of exposure would be infinitely greater in the case of the latter than in the case of the retailer, because his customers are fewer in number, and a conviction would in all probability cause him to lose a considerable portion of them.

The power of appeal will probably be retained, but this is likely to prove some obstacle to the effectual working of an Act the enforcement of which is left to individuals. A man may be willing to undergo some trouble and expense from philanthropic motives, if he can see a limit to his expenditure of time and trouble, but he will hesitate to embark in an affair which may not be settled for weeks, and which may ultimately involve him in odium as well as in loss of money.

The appointment of analysts is vested by the bill in vestries and boards, the members of which are not unfrequently tradesmen or intimately connected with them, and it does not seem probable that these will be particularly anxious to appoint a man to test the purity of their goods; consequently it may be predicated with great certainty that in many parishes they will never be made to see the necessity for appointing such an official; and even where members would be willing enough to elect an analyst if it were compulsory on them to do so, they will hesitate and avoid doing so if it is optional, when they know that the tradesmen on whom depends their re-election will in every probability select other representatives to fill the place of those who saddled them with inquisitors. Besides there is no good reason why, if it be desirable in the interest of the public that analysts should be appointed that the appointment should not be compulsory. Then, again, the analyst, even when appointed, is not bound to visit shops and purchase specimens, and putting the act in force against adulterators is left to the public at large, not a very satisfactory guarantee for its enforcement, seeing that what concerns people in general is not considered the business of any individual in particular. No doubt vestries may make it a condition on appointing an analyst that he should do this, but for the reasons stated above it is not likely that they will. In Paris, where the health of the public is considered of some importance, the authorised officials are the responsible persons, and it is no uncommon circumstance for one of these to stop a milkman in the streets, and carry away a certain quantity of his milk for analysis.

As regards the punishment for acts of adulteration, the amount of the fine is of secondary importance; the real punishment is in the exposure and the consequent loss of custom. The mode of publication of the second conviction is left to the judgment of the magistrates who hear

the case, who will, we fear, be content to adopt that which is adopted by the Act, viz. publication in one or more newspapers. Now, thoroughly effectual as this might be in checking adulteration among the tradesmen whose customers are chiefly among the higher class, it would be of little effect among those who live in poor neighbourhoods, the inhabitants of which never read a newspaper. We repeat, that the only effectual method of exposure is to adopt that which is pursued in Paris—having the offence and the punishment printed at the offender's expense, and exhibited in his shop window for a fixed period.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

New Process for the Separation and Estimation of Phosphoric Acid. By M. G. Chancel.[1]

M. Chancel's new process is founded on the complete insolubility of the phosphate of bismuth in liquids which contain nitric acid even in considerable quantity. When a solution of acid nitrate of bismuth (so dilute that it is no longer rendered turbid by water) is added to a liquid containing a phosphate, a very dense and beautiful white precipitate is formed, which falls very rapidly and leaves the liquid perfectly clear. A great many analyses and syntheses have demonstrated that the composition of the precipitate so obtained is constant, and is represented exactly by the formula

$$Bi\ O_3.PO_5.$$

The salt, therefore, is a neutral phosphate, since the triatomic molecule of the oxide of bismuth replaces the three molecules of water of the tribasic phosphoric acid.

The neutral phosphate of bismuth is quite insoluble in water[2], and dilute nitric acid either cold or boiling, but soluble in liquids containing much of the ammoniacal salts. The filtration of the liquor in which it may be suspended requires no particular precautions, and a little washing with water is sufficient to remove any traces of foreign matters in the solution; it dries very quickly, and as it is infusible at a red heat, it may be ignited without fear in a platinum crucible. The recent researches of Dumas give 210 as the equivalent of bismuth, and therefore a salt of the above composition will contain 23·28 for 100 of anhydrous phosphoric acid.

Pyrophosphoric acid $p\ PO_5$ is also completely precipitated from a cold solution by the acid nitrate of bismuth, forming a white precipitate much more bulky than that obtained with the tribasic acid. On analysis this precipitate gives results which perfectly agree with the formula[3]

$$2\ Bi\ O_3.\ 3\ p\ PO_5,$$

in which the relation of the oxygen of the base is to that of the acid as 2 is to 5. The compound is therefore a neutral pyrophosphate of bismuth: it contains 31·28 of the base for 100 of pyrophosphoric acid. Experiments demonstrate that it is the pyrophosphoric and not the tribasic acid which exists in the precipitate obtained under the conditions indicated; for if after washing the precipitate with cold water it is treated with sulphuretted hydrogen, sulphide of bismuth is formed which can be separated by filtration, and then, after removing the excess of sulphuretted hydrogen, the solution gives a white precipitate with the salts of silver. But in an analytical point of view, the most interesting property which this pyrophosphate presents, is its complete and instantaneous transformation into the tribasic phosphate, $BiO_3\ PO_5$, when heated with an excess of the acid nitrate of bismuth. It is sufficient to heat the liquid to the boiling point, at which the precipitate immediately changes its appearance and becomes much more dense. Washed and dried it has then the composition $BiO_3\ PO_5$, and decomposed by sulphuretted hydrogen it furnishes an acid which precipitates the salts of silver yellow.

The metaphosphates behave in just the same way: the precipitate only requiring a longer boiling to be completely changed into the ordinary phosphate. Decomposed by sulphuretted hydrogen it gives an acid which does not coagulate albumen, and which precipitates the salts of silver yellow after having been exactly neutralised with ammonia. All these points justify the conclusion that in estimations of phosphoric acid in the form of phosphate of bismuth it is not important to consider under what modification the acid may exist in the substance to be analysed.

The above process is not only complete but very delicate; and as the precipitation is extremely rapid in a hot solution, the liquid becoming clear almost instantaneously, it will be easy to estimate phosphoric acid with a standard solution of the acid nitrate of bismuth.

Preparation of the Reagent.—The salts of bismuth having a great tendency to split up into basic insoluble salts and acid salts, the reagent made use of must be sufficiently acid and diluted as no longer to become turbid either by boiling or by further additions of water. These conditions will be realised when the solution will contain 10 or 12 equivalents of nitric acid, supposed anhydrous, for 1 equivalent of oxide of bismuth $Bi\ O_3$. A convenient test solution for qualitative experiments, as well as quantitative determinations, may be prepared by dissolving one part of pure crystalline subnitrate of bismuth ($BiO_3.\ NO_5+Aq$) in four parts of nitric acid sp. gr. 1·36, adding to the solution 30 parts of distilled water, and then boiling and filtering if necessary. Each cubic centimetre of such a solution will precipitate from 7 to 8 milligrammes of phosphoric acid.

The separation and estimation of phosphoric acid in the presence of various bases is very simple. The matter to be analysed is weighed; if insoluble in water, it is treated by nitric acid, avoiding too great an excess. The solution is then diluted with distilled water, and the acid nitrate of bismuth is added until nothing more is precipitated. The whole is then boiled, filtered, and the filter washed with boiling water until the washings are no longer coloured by sulphuretted hydrogen. The precipitate is now carefully dried, and removed from the filter as completely as possible. The filter is incinerated by itself, and the weight of phosphate left is added to that of the principal precipitate, which is calcined at a red heat and weighed when completely cold. The weight of the precipitate, multiplied by 0·2328, will give the weight of the phosphoric acid contained in the substance submitted to analysis.

The above process, which gives remarkably exact results, only requires that the liquor shall be free from chlorides and sulphates. If these be present, the chlorine and sulphuric acid must be removed before the nitrate of bismuth is added.

[1] *Comptes-Rendus*, t. l. p. 417.

[2] It is said in Gmelin's *Handbook*, vol. iv. p. 434. to be either a white insoluble powder which fuses to a white enamel, or a crystalline salt soluble in water.—Ed.

[3] M. Chancel represents ordinary or tribasic phosphoric acid by the symbol PO_5, pyrophosphoric or bibasic acid by $p\ PO_5$, and meta- or mono-basic acid by $ss\ PO_5$.

TECHNICAL CHEMISTRY.

The New Zealand Iron Sand, and a Discovery in Iron Metallurgy.

Mr. Robert Mushet, in a long letter to the *Engineer*, expresses an opinion that the true key to the mystery of the excellence of the Danemora and other irons is the presence of titanium. Some years ago his father, Mr. David Mushet, discovered some crystals of a titanium compound in the hearth of a Norwegian blast furnace, and some of the same have since been found in furnaces in the Forest of Dean and Cleator districts, both celebrated for the excellence of their iron and the steel made from it. "Now," he continues, "as all the recognised ingredients of the ores of these districts were common also to the ores of other districts whose iron and steel were not in any way remarkable for excellence, it occurred to me that the unrecognised ingredient titanium might possibly be the true key to the profound mystery which had so long defied the efforts of chemists and practical men to unravel. I immediately procured some ores of titanium, for the purpose of experiment, and which ores I found, however, were all but unobtainable, so that I had to pay 16*s.* per ounce for some rutile, and 5*s.* per ounce for ilmenite. I was assured also that I must never expect to procure these ores in quantities beyond a few pounds' weight at the most, as they were almost the rarest of minerals. But I went to work, and by alloying small quantities of titanium with iron and steel I obtained surprising results, which at once convinced me that I was upon the right track at last. I now had the iron ores of the districts I have named carefully examined for titanium, and I found that all of them contained titanic acid, and that whichever ore most abounded in titanic acid, the iron and steel produced from that ore was the most celebrated and valuable. In reducing likewise the ores of iron and titanium I found that a peculiar slag, or scoria, was always obtained, and of such a remarkable character that it was impossible, when once seen, ever to mistake it for any other kind of iron slag; and from the colour and appearance of this slag I could at length, by experience, determine with tolerable accuracy the per centage of titanium, and therefore of titanic acid, in any given specimen of titanium ore or titaniferous iron ore. And now the whole mystery of the Danemora iron was at once elucidated, and its explanation is this—the magnetic iron ore from which the Danemora iron is prepared contains a larger percentage of titanic acid than other ores from which the inferior brands of Swedish iron are obtained, and the bar iron obtained is therefore more largely alloyed with titanium.

"Moreover, as titanium is perhaps the most difficult to fuse of all the metals, its alloy with bar iron requires a higher temperature for its fusion than that required for the fusion of bar iron destitute of such an alloy, and it is well known that the best Danemora iron, in the state of iron, is more difficult to melt than any other charcoal bar iron. It has also been observed by the steel trade that steel irons which require "much melting," *i. e.* which are difficult to melt, yield cast steel possessing great "body," *i. e.* powers of endurance when made into a tool. If any chemist will be at the pains of analysing the steel irons used in Sheffield, and seek especially for their percentage of titanium, he will find that their market value is in exact proportion to the percentage of titanium they respectively contain.

"It will, I am aware, be objected that chemists have as yet detected no titanium in these irons. I grant this, and I will explain why it has been so. Chemists confound the titanic and silicic acids one with the other, and, besides this, the insoluble residuum is likewise a form or compound of titanium. I will cite a case in point which completely confirms and proves my position. An extraordinary magnetic iron sand was brought to England from a volcanic district in the South Seas. Some of this ore was sent to me, and I perceived at once that it was an ore of titanium. On testing it by my processes, I found that it must contain at least 8 or 10 per cent. of titanic acid. I received at the same time an elaborate analysis of this ore, performed by an able chemist, who read a paper on the subject before the Chemical Society, and which analysis gave not a trace of titanic acid. Subsequently I found that another chemist had fully confirmed my experiments by finding over 8 per cent. of titanic acid in this iron ore.

"The excellency, then, of this extraordinary magnetic iron sand is due, first, to its large percentage of titanic acid, and, secondly, to its freedom from impure earthy mixture, which more or less deteriorates the quality of all iron ores, whether titaniferous or not. I have from this ore manufactured steel of surpassing excellence; samples of which are in the hands of the fortunate owner of the deposit, the value of which for steel and iron-making is incalculable. The analogy between this ore and that of Danemora has already been observed by parties acquainted with the manufacture of Swedish iron; but the explanation of the similarity was reserved for me to give. Until my discoveries upon this subject, titanium has only been alluded to as a pernicious ingredient in iron ores or iron, causing redshortness, &c. One chemist alone has remarked that titanium in small quantities does not appear to affect the quality of iron injuriously, and this remark I find in an almost obsolete French work on chemistry. The celebrated Damascus blades are made from iron reduced from a highly titaniferous iron ore. The Wootz ore of India is more titaniferous than that of Danemora. The Elba iron ore is moderately titaniferous, and so also is the Brush iron ore of the Forest of Dean. Iron alloyed with titanium possesses a degree of body and durability unknown in ordinary bar iron of good quality. First-rate steel can only be made from iron containing titanium. There is a spurious, ductile, and easily workable steel which owes its usefulness to the presence of manganese; but between which and the titanic steel there exists as wide a difference, in point of excellence, as there is between common hot-blast Scotch pig-iron and the best Shropshire or Blaenavon cold-blast iron.

"This difference is well known to the Sheffield trade. Titanium steel has "body." Manganese steel has little or none; but it is ductile and hardens well, and is cheap besides, and can be applied to inferior purposes. Not that the Sheffield steel makers ever dreamed about titanium; but what they call "body" is in intelligible language rendered correctly by the term titanium; and to the fact of this metal existing in alloy with Danemora and other Swedish bar irons to the extent of from one quarter per cent. to about one or one and a half per cent. is mainly due the rise, progress, and present prosperity of Sheffield and its manufacturers.

"When pure grey cast-iron is alloyed with titanium in certain proportions, it may, when cast into ingots be drawn into bars of great strength and tenacity. I have thus drawn an ingot of grey cast-iron 3 in. square into bars ¾ in. square, and perfectly sound.

"The specific gravity of titanium has been most erroneously assigned by chemists as 5·3. It is in reality a

metal somewhat heavier than iron, and that steel which contains a large alloy of titanium is consequently found to have a higher specific gravity than other steel. It may be objected that small proportions of titanium, in alloy with iron, cannot produce a marked effect. To this I reply that with one half per cent. of carbon, and under that proportion, are produced nearly all the marketable varieties of bar iron and steel with which we are familiar, and it is also certain that one half per cent. of phosphorus renders bar iron crystalline, and one half per cent. of sulphur occasions redshortness; therefore that so small a quantity as one half per cent. of titanium should constitute the excellence of steel iron is not at all an anomaly. Magnetic iron ores always contain some titanic acid, and such is its efficacy in improving the quality of iron, that the most impure magnetic ores, abounding with pyrites, nevertheless, yield iron of a superior class. If the iron used in the manufacture of rails was prepared from pig-iron, smelted from ordinary iron ores, with the addition of a tenth part of titanium, or even one-twentieth, the rails thus manufactured would be at the least four times more durable than they are found to be under the present processes of manufacture. This is only one of the many important results which the discovery of the effects of an alloy of titanium upon iron will lead to. The deposit of titanium ore of the iserine variety, to which I have alluded, extends twenty miles in length by half a mile in breadth, and has no bottom at four yards in depth. It is all of one uniform quality, in the state of iron sand, so minutely divided, that of half a ton which I have had, the whole of it readily passes through the meshes of a sieve of 3600 holes to the square inch, that is to say, the largest grains are not so much as one 3600th part of an inch[1] in diameter. From my experiments with iserine heated and immersed in water, I am of opinion that the whole of this extraordinary deposit of iron sand has been, when at an intense temperature, suddenly quenched in water. It probably existed in the interior of a volcano, into which at some epoch an irruption of the sea has taken place, and the sand has been thrown out by the force of the explosion which must have ensued. The region is volcanic, and there are lofty extinct volcanoes near the locality of the deposit.

"Reckoning 30 cwt. per cubic yard as the weight of this sand, the number of tons in the area already ascertained of this deposit will amount to 185,856,000 tons, a quantity sufficient to furnish a supply for all the furnaces in England with ore for twenty-five years."

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY, 5 *April* 1860.

DR. A. W. MILLER, *in the Chair.*

DR. ANDREWS, *F.R.S.* delivered a discourse *On Ozone.* Van Marum appears to be the first who observed that oxygen through which electrical sparks have been passed acquires a peculiar odour and the power of attacking mercury. This subject attracted no further attention for upwards of half a century after the publication of Van Marum's observations.

In 1840 Schönbein made his first communication on ozone to the Academy of Munich. It was entitled *Observations on the Odour developed in the Electrolysis of Water, and the discharge of Common Electricity from Points.* In this important paper, he states that in the electrolysis of water, an odorous substance appears at the positive pole, that this substance may be preserved for a long time in well-closed vessels, and that its production is influenced by the nature of the metal which serves as the positive pole, by the chemical properties of the electrolytic fluid, and by the temperature of that fluid or of the electrode. The same effect was produced by holding a strip of platina or gold near the knob of the prime conductor of an electrical machine in good order. With great sagacity he also recognised the identity of the peculiar odour which accompanies a flash of lightning with that under consideration. In this paper Schönbein supposes the odoriferous principle, for which in a note at the end he proposes the name of ozone, to be a new electro-negative element belonging to the same class as chlorine and bromine. In a subsequent memoir, he hints that it is not only an elementary body, but a constituent of nitrogen.

Schönbein soon afterwards discovered that the same substance is produced when phosphorus is slowly oxidised in moist air or oxygen gas.

In the following year he returns to the consideration of the nature of ozone, and partly from his own observations, partly from experiments communicated to him by De la Rive and Marignac, he concludes that ozone is not a constituent of nitrogen nor a simple body, but an oxide of hydrogen, different from the peroxide of hydrogen of Thénard; and draws the conclusion that its constitution must be similar to that of chlorine, which possesses analogous properties. He is therefore led to adopt the old hypothesis of Berthollet regarding the compound nature of chlorine.

In a communication made to this Society by Dr. Williamson, in May 1845, that distinguished chemist gave an account of some experiments from which he concluded that the peculiar properties belonging to the oxygen set free by the agency of the electrical current, are produced by the admixture of a peroxide or acid of hydrogen, and that by the action of phosphorus on atmospheric air the same substance is not produced.

About the same time, or a little earlier, an important set of experiments on the same subject was communicated by M. Marignac to the Academy of Sciences. The following are the chief conclusions to which Marignac arrived:—

1. In the decomposition of water charged with sulphuric acid by the pile, the production of ozone is independent of the presence of nitrogen.

2. Air perfectly dry does not produce ozone when passed over phosphorus, nor air deprived of its oxygen, even if moist; nor pure oxygen, nor carbonic acid, nor hydrogen.

3. Ozonised air loses its properties when heated to a temperature of from 300° to 400° C.

4. Ozone is not absorbed or altered by water, concentrated sulphuric acid or chloride of calcium.

5. It is absorbed with great facility by iodide of potassium. (The last three properties had been already discovered by Schönbein.)

6. Ozone is easily absorbed by the metals, but if it be perfectly dried it yields nothing to silver, nor to copper, nor even to zinc.

In a subsequent inquiry conducted by Marignac, in conjunction with De la Rive, the important observation was made that ozone is produced by the action of the electrical spark on pure and dry oxygen.

A very elaborate memoir on the action of the electrical spark upon oxygen, by Frémy and Becquerel, was published in 1852 in the *Annales de Chimie.* In this memoir the authors show that pure oxygen, contained in a tube inverted over a solution of iodide of potassium, is entirely absorbed by that liquid if electrical sparks be passed for a sufficiently long time through the gas. This fact is certain, and I have myself had occasion frequently to verify it. But I have not been able, in repeated trials, to convert the whole of a given volume of dry oxygen into ozone by passing the electrical spark through it.

It is perhaps scarcely necessary for me to do more than allude to the experiments of Baumert, and to those which I myself communicated some time ago to the Royal Society. It may be sufficient to state that Baumert arrived at the conclusion that the active substance which accompanies electro-

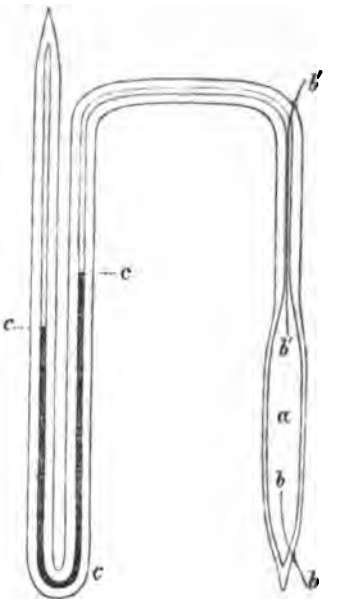
[1] 60th part of an inch?—ED.

lytic oxygen is a teroxide of hydrogen, and different from the substance produced by the electric spark on pure oxygen. My own experiments led to a different result. I found that the iodine corresponded exactly to the weight of the ozone, and, further, that in the decomposition of large quantities of ozone by heat (quantities which, if ozone were a teroxide of hydrogen, should have yielded in different experiments from 10 to 14 milligrammes of water) not a trace of water was formed. In other respects, the properties of ozone prepared by the electrical discharge and by electrolysis, were found to be the same.

Schönbein having finally rejected both his earlier views of the constitution of ozone, and adopted the view (first suggested I believe by Marignac) that ozone is an allotropic form of oxygen, has recently given a remarkable extension to this hypothesis. Having observed that on agitating air containing ozone with a certain quantity of the peroxide of hydrogen, the ozone reactions disappear, and at the same time the peroxide is reduced to water, he concludes that oxygen, as it exists in ozone and in the second atom of the peroxide, is in two active but opposite states. The former he designates negatively-active, the latter, positively-active oxygen; or ozone and antozone, symbolised by Θ and $\oplus$. From the union of an equivalent of positively active oxygen with an equivalent of negatively active oxygen, common or inactive oxygen is formed. He also considers the higher atom of oxygen in the peroxides of manganese, lead, nickel, cobalt, bismuth, and silver, as also in the manganic, chromic, and vanadic acids, to be in the negatively active or ozone condition, while in the peroxides of barium and strontium, and of the alcaline metals, it is in the positively active or antozone state. Pushing these views still further, he ventures to express in symbols the supposed composition of chlorine as $MnO + \Theta$, corresponding to that of the peroxide of manganese $MnO + \oplus$.

The speculations of Schönbein bear a striking resemblance to certain views of chemical changes which were proposed some years ago by the President of this Society. In a paper communicated to the Royal Society, and afterwards published in its *Transactions*, Mr. Brodie suggests that in many chemical reactions different equivalents of the same element are thrown into opposite polar conditions, and he employs almost the same form of symbol as Schönbein to represent these opposite conditions. He also distinguishes between the isolated element, the particles of the element at the moment of their chemical separation or synthesis, and the combined element.

The Lecturer then proceeded to state that his object was to determine the volumetric relations of ozone to common oxygen, for the purpose of throwing some light on the true nature of this singular body. He would first assume the allotropic hypothesis to be true; on that assumption the question would resolve itself into the determination of the relation which the density of ozone bore to that of oxygen. The first experiments were performed with ozone obtained by the electrolytic decomposition of dilute sulphuric acid, in which case the amount obtained is not above the 200 or 300th part of the volume of the gas, under the most favourable conditions. The determination of such a change of volume as this was a most difficult matter. But after some time he succeeded in devising an apparatus which proved that a very considerable expansion occurred when ozone was changed into oxygen. This consisted of a bent tube containing a rather large reservoir. This tube is connected again with a syphon-tube of capillary bore. It is easy to fill this apparatus with carefully dried oxygen by displacement, and when certain that the whole of the tube is filled with oxygen, one leg of the syphon-tube was filled with sulphuric acid, and the lower end of the tube was sealed by directing a blowpipe jet upon it. A tube of the kind above described when the reservoir is large is so delicate that the variations in the level of the sulphuric acid are pretty nearly in proportion to the variation of the atmospheric pressure, and it was found that a variation of one millimetre or one twenty-fifth of an inch in the height of the column of sulphuric acid corresponded to a variation of one five-thousandth of the



a. The reservoir for the oxygen gas.
b b. b' b'. Platinum wires, sealed into the tube.
c c c. Column of sulphuric acid in the syphon tube.

volume of gas, or to the 20-thousandth part of its volume if read to a quarter of a millimetre. In this form of apparatus there was no difficulty whatever in ascertaining that a notable increase in bulk occurred when the ozonised oxygen was heated. The vessel was placed in an air bath over a lamp, and a temperature of 300° C. readily obtained. And in this way it was found that, in the case of electrolytic oxygen, after heating the tube, an expansion of 8 or 10 millimetres frequently occurred, as measured by the sulphuric acid in the syphon-tube.

Having very briefly described the form of the apparatus employed, the Lecturer proceeded to consider the best means of producing ozone and the change which took place in oxygen under the influence of the electric spark or discharge. Rühmkorff's coil had not been used in any of these experiments, it being entirely inapplicable, owing to the heat destroying the greater part of ozone as soon as formed. Even the spark derived from the ordinary machine interfered very much with the production of ozone. The *spark* was obtained from an electric machine about 18 inches diameter, placed opposite a fire and turned by means of a large multiplying wheel. The machine performed 350 revolutions per minute, and gave in the same time 600 dense sparks, and decomposed sufficient water to produce ·0002 cubic centimetres of the mixed gases. The other form of discharge, which was by far the most important, was the silent discharge produced by passing the electric discharge between two fine points without any visible phenomenon in daylight. (If it were possible to produce a discharge which would be invisible in the dark, he believed we might proceed much further in the production of ozone). This was obtained by connecting one of the platinum wires with the machine and the other with the ground and turning the machine rather slowly.

The Lecturer next proceeded to give the details of the experiments which he had performed in conjunction with Professor Tait. An apparatus similar to the one above described was taken, and oxygen gas prepared from chlorate of potash was passed through it, several precautions being taken

to insure the oxygen being perfectly dry and containing no admixture of atmospheric nitrogen. Having filled the apparatus, into which were previously fused a couple of platinum wires at convenient distances, it was sealed in the ordinary way. The height of the sulphuric acid column was read off, and after passing the electric discharge through it for about twenty minutes, it was found that the sulphuric acid fell from 1 to 3 inches according to the length of time. The same vessel was then taken and introduced into the air bath, heat was applied to it, and it was found that the gas returned to exactly the same volume as before. This experiment had been repeated with the same tube for 20 or 30 times. The contained oxygen had been changed into and from its ozone condition without any loss of its original volume.

The Lecturer then proceeded to give an account of the principal results which he and Professor Tait had obtained. They were briefly as follows: — When the silent discharge was passed through perfectly pure and dry oxygen, its volume changed rapidly at first, and afterwards more slowly, until it attained a contraction of one-twelfth of the original volume of the gas; that was the extreme result, and only to be obtained when the oxygen was perfectly pure and free from nitrogen. And when this ozone is heated to 300°C. it is restored to its original volume. This extreme contraction also slowly diminishes if the vessel is allowed to stand for some days, but whether this diminution would ever come to an end had not been determined.

The volumetric results which were obtained when metals and other bodies were brought into contact with ozonised oxygen gas were next described. The details of a great many experiments were described which had been undertaken with the view to ascertain what contraction was experienced when the ozone in one of these tubes was absorbed by iodide of potassium, mercury, or other substance, but the result in every case showed that there was not the slightest contraction in the volume of the gas in the tube when the ozone was removed from the oxygen, the volume of ozone thus appearing to be *nil*. These results were considered to be so remarkable and so entirely inexplicable in any received view of the subject that two other series of experiments of a very laborious kind were undertaken in order to test the correctness of this conclusion with greater accuracy, but the uniform result of all these experiments indicated *no volume* for the ozone within the limits of the errors of experiments; or to express it otherwise on the allotropic hypothesis, it gave an *infinite density* to ozone — that of a fluid or a solid rather than of a gaseous body.

The action of the electric discharge on compound gases was next described. The most remarkable of the results so obtained was when pure carbonic oxide was submitted to the action of the silent discharge. Upon passing the silent discharge through a sealed tube of carbonic oxide, it was found that in the course of a quarter of an hour the positive wire was covered with a bronze coloured deposit, while the negative remained unaffected, unless the experiment was continued for a long time, thus appearing to indicate polar action in the decomposition of the gas. If the action were continued for sixty hours, the gas would be completely decomposed by the action of the silent discharge, and would contract to one third of its volume. As it proceeds, the negative wire would become tinged, and the tube coated with the yellow body; it was impossible to determine the nature of this substance by any chemical analysis because of its extremely small quantity; it can only be ascertained by analysing the residual gas. It appears to be soluble in water, for if the wire with this deposit upon it were moistened with water the deposit would entirely disappear and the platinum recover its colour.

In conclusion, the Lecturer made some remarks upon the different theoretical explanations that could be given of results apparently so singular. About the general facts there could be no doubt at all, but with regard to the key to the phenomena that was another question. If the allotropic hypothesis of the nature of ozone were adopted in its simplest form, there seems only one way of accounting for its absence of volume, namely, by supposing that when ozone comes in contact with iodide of potassium, one part of it changes into oxygen and the other part combines with the liquid, and that these two are so related to each other that the expansion due to one is exactly equal to the contraction due to the other. On this view, we should have no means of determining what the density of ozone really is, but its density must be greater than that of oxygen. Finally, we have another possible view which will explain the phenomena, and that is that oxygen gas may be a compound body and undergo decomposition.

The Chairman expressed the thanks of the Society to Dr. Andrews, who had come over from Belfast for the purpose of giving this lecture.

Professor Williamson had very great pleasure in listening to Dr. Andrews; this certainly appeared to him by far the most careful and complete quantitative investigation published on the subject. He agreed with Dr. Andrews when he said that facts must go before theory; and in devoting himself to these volumetric researches his experiments seemed admirably calculated to secure accuracy. The subject of ozone had attracted the attention of many scientific men, and had led to so many misconceptions and popular fallacies of a really mischievous kind (for every error must be mischievous more or less) that he thought it desirable to rectify, to some extent, one or two of the more important of those popular errors or fallacies. He should be very sorry to detract in any way from the merits of M. Schönbein. We owed to him the original stimulus and many original facts; but he must refer to the wonderful number of theories which M. Schönbein had propounded, and with the wonderful rapidity with which he changed them. He (Professor Williamson) did not know anything upon which so many different theories have been promulgated. He thought the word ozone was applied to a number of reactions and effects which are not as yet proved to be. Some persons assumed that whenever iodide of potassium was decomposed that ozone was present. Now, the difficulty in chemistry was to find a substance which did *not* decompose iodide of potassium. Every acid present in the air stronger than carbonic acid must produce that particular effect which is attributed to ozone. But there is also an exceedingly numerous class of oxidising agents, such as hyponitrous acid, and some organic compounds such as turpentine, &c. which appear to have been first noticed by Schönbein himself, and any of these substances present in the air would produce the particular effect which is considered to be a proof of the presence of ozone. He would wish to allude specially to one part of Dr. Andrews' papers, namely, the theoretical conclusion to his most exceedingly valuable results. He hoped it would not be thought presumptuous in him to enter into that subject, which was really one of considerable importance. He alluded especially to the circumstance so clearly proved by Dr. Andrews, that when ozone is *decomposed* by a metal, or by iodide of potassium — he would not say *condensed* but *decomposed* — that no diminution of volume takes place. Now he should be disposed to submit to Dr. Andrews' consideration a mode of stating that fact different from the one which he had adopted, that is, he should consider it as merely a removal of oxygen from that compound, or from that condition in which it produced the reactions of ozone. He agreed most fully that the fact of no diminution of volume taking place when ozone was removed from the gaseous mixture, proved that the oxygen which was taken away was combined with something else in the tube. Whether with another atom of oxygen, or whether with water or something else, the hypothesis would still be consistent with the fact. He considered that we were forced to believe that the particular oxidising gas must have contained some compound of oxygen, and he must confess that he should consider ozone to be a teroxide of hydrogen rather than allotropic oxygen. He thought that the experiments which Professor

Bunsen made some years ago with such well known care, showed as clearly as can be that ozone formed by electrolysis was something more than oxygen, and was not the only ponderable matter carried over.

Dr. Andrews stated that he had omitted one possible cause and that is the consideration that oxygen might contain a small portion of some other body, which might possibly be an explanation of the whole phenomena. There was only one point to which he wished to refer; he could not imagine that any form of ozone obtained by electrolysis contained hydrogen. No doubt ordinary oxygen did act on the acid solution of iodide of potassium, but it only amounted to one-twentieth part of the effect observed, and, moreover, would have effected both sides of the equation. Further, the numerous experiments he had made for the purpose of detecting the presence of water as a result of the decomposition of ozone have all failed whether the ozone was obtained by the electric discharge or other processes. In fact, he could not conceive the possibility of the hundredth part of the amount of hydrogen being present in his tubes of oxygen, which would be necessary on the assumption that ozone was a teroxide of hydrogen.

Dr. Hofmann was extremely interested in the peculiar manner in which the electric discharge acted upon the carbonic oxide. Professor Buff and himself had made a series of experiments upon a different principle; they wanted to obtain volumetric results capable of being exhibited as lecture experiments. They used the discharge from a Rühmkorff's coil. He wished to know from Dr. Andrews whether the bulk of the gas in the carbonic oxide tube was increased, and what was the volume of the gas after the decomposition had taken place.

Dr. Andrews could not answer Dr. Hofmann's question very definitely, as the experiments were not quite completed. With regard to the results, if the discharge was passed through the gas for about sixty hours, until the gas is contracted to about one third of its original volume, the residual gas consisted of carbonic acid, oxygen, and carbonic oxide. The proportions were determined, but were not given, as the results were not always identical.

Dr. Hofmann stated that the passage of the spark current through carbonic oxide did not produce any effect within twenty-four hours. With regard to sulphurous acid, there was for some time no effect produced with the spark current; but after two or three hours a contraction took place, and a peculiar yellow deposit was obtained. He had succeeded in producing a very considerable contraction; and the deposit was obtained in such quantity that they were enabled to examine it. It was found to be a compound of anhydrous sulphuric acid and sulphur. On addition of water, sulphur was separated in flakes, and the solution contained free sulphuric acid. It would be interesting to compare the production of the yellow body, in the case of the carbonic oxide, with the production of this substance from sulphurous acid.

PHARMACEUTICAL SOCIETY, 4 *April* 1860.

T. N. R. Morson, *Esq. President, in the Chair.*

The first paper read was *On Tallicoonah Oil*, by Mr. R. Clark. This article, known also as *Croupee* and *Coondee*, is obtained from the seeds of a tree which grows abundantly at Sierra Leone, and other places on the west coast of Africa. The fruit of the tree, which ripens in March and April, is a globular capsule, containing four or five seeds. These latter are dried by the natives, who then beat them into a pulp, which is boiled with water in large clay pots, and the oil is skimmed off as it separates. In some places the seeds are roasted before they are beaten into pulp. The oil is preserved by the natives in large wooden troughs furnished with lids. When carefully prepared it burns well, but, as usually obtained, it gives a smoky flame. It is a drying oil, and answers well for paints. The price of it on the Gold Coast is 1*s.* 9*d.* per gallon, and at Cape Coast 2*s.* per gallon. Owing to the difficulty of introducing a new article to commerce, no great quantity had been exported from Africa, but some had been sent to America, where it had fetched the same price as palm oil. If a demand for it were to arise, very large quantities could easily be obtained. It is soluble in ether. Alcohol dissolves a part of it, and separates a concrete fat. The natives use the oil as an anthelmintic, administering from one to two ounces to robust adults. The effects resemble those produced by castor oil. According to the author, it must be used with judgment, for an overdose excites severe vomiting and cold sweats. For ascarides it is very effective, when used in the form of an injection. It is used, besides, as a liniment for rheumatism, and as an application in some skin diseases. The oil has an extremely bitter taste, which seems to be shared by all parts of the plant from which it is obtained, and probably belongs to an alkaloid which has not yet been separated.

Mr. Hanbury said that the seeds had been imported in large quantities, and he had seen some hard fat which had been obtained from them by hot-pressing. The residual cake, he thought, would yield the bitter principle.

The next paper was on *Taraxacum*, by Mr. T. B. Groves. The author said he had collected the plant at all seasons of the year, and he believed that October was the best month to collect it for the extract. He had also prepared some extract according to the process given in the Pharmacopœia, and had found that the extract so prepared had no similarity to any in commerce. It was an opaque tenacious mass, with a mawkish taste, which made with water a whitish opaque fluid. According to Pereira, the extract is bitter and aromatic, but that found in commerce is always sweet. The author recommends the following process for the preparation of the extract. The roots collected in October are sliced and pressed, by which means about half their weight of liquor is obtained. This is heated and then strained, afterwards evaporated for some time and strained again, and then the evaporation continued to a proper consistence. Such an extract can be preserved for any length of time by placing it in covered pots, sprinkling the surface with alcohol, and hermetically sealing the pot by means of a strip of sticking plaster. The fluid extract should be made from the fresh roots collected at the same time of the year. They should be quickly cleaned, sliced, and pressed. If half their weight of liquor is not obtained, it should be made up with water. The juice must now be evaporated to half its volume, and one fourth of spirit added. It must now be filtered and the residuum gently pressed. The author insisted on the necessity of some single process for the preparation of the extract. In consequence of its being prepared in various ways from roots collected at different times, it was difficult to find two specimens quite alike. The liquors differed still more. He hoped the forthcoming Pharmacopœia would rectify this state of things by giving authoritative directions for the preparation of both liquor and extract. The consequences of the differences in these articles are sometimes disastrous to a druggist who has not a "historic name" to sustain his credit, for patients always believe that the medicine first made up from a prescription is correct, and any variation in appearance or taste, afterwards, is the result of a mistake on the part of a dispenser.

The Chairman agreed in the necessity of uniformity in the mode of preparing these medicines, and Professor Bently reiterated his opinion that the proper time for collecting the roots was the spring.

Mr. Haselden then made some remarks on the preparation of plasters. He objected to the form for *emplastrum opii* in use, which makes a plaster which runs, and goes through the leather. He thought the gum *thus* might be advantageously replaced by *emp. resinæ*, and the opium by a solution of morphia. He recommended that the following form should be adopted in the new Pharmacopœia:—

Lead Plaster	ʒvj.
Resin Plaster . . .	ʒiv.
Acetate of Morphia . .	ʒj.
Acetic Acid	℥lv.
Water	ʒiv.

Dissolve the morphia in the acid, diluted with the water; add them to the melted plasters, stir and keep hot until all water has been driven off. The *emplastrum belladonnæ* was objected to on account of its disagreeable smell and its want of adhesiveness necessitating a margin of lead plaster. In the Pharmacopœia of 1836 the extract of belladonna was ordered to be mixed with resin plaster, but this made an irritating instead of an anodyne application, and in the next Pharmacopœia the quantity of extract was doubled, and it was united with soap plaster. The result was a soft plaster which would not adhere. The author said that *atropine* might be used in this case to replace the extract of belladonna, and the form he suggested was the following:—

Lead Plaster	3vj.
Resin Plaster	3iv.
Atropine	grs.iv.
Acetic Acid	3ij.
Water	3iv.

The atropine should be dissolved in the acetic acid and then mixed with the melted plasters, and the heat continued until all the water and acetic acid had evaporated. No trial had been made of this plaster, but the one prepared with morphia had been tried, and found as efficacious as the plaster of opium.

The CHAIRMAN said that there was one objection which he thought was fatal to the use of atropine in plasters. It was completely destroyed at a temperature a little above that of boiling water. There was no such objection to the use of morphia, but he had some doubts of its value when locked up in a hard resinous plaster. The value of opium in a plaster he thought was much over estimated. He had had a man engaged in pulping 2 cwt. of opium, an operation which lasted several hours, during which time the man had his naked arms constantly immersed in a strong solution of opium, and yet he had never seen any narcotic effect produced.

Mr. WHIPPLE said he had seen men affected by the evaporation of extract of opium.

Mr. ROBBINS and Mr. HANBURY told of cases in which severe effects had followed the application of a belladonna plaster. In that related by Mr. Robbins death almost ensued.

The next paper was *On the Adulteration of Carmine*, by J. ATTFIELD, *Demonstrator of Chemistry at St. Bartholomew's Hospital.*

The object of the author in this communication was to draw attention to the fact that carmine is largely adulterated with dichromate of lead, and to point out the enormous extent to which vermilion is used for the same purpose.

After describing what commercial carmine should be, and noticing its use by artists, confectioners, red ink makers, &c. the author proceeded to detail the method adopted in the examination of fifteen samples of this pigment, obtained from the retail shops of chemists and druggists, and artists' colourmen, in various parts of London. It mainly consisted in dissolving out the carminic acid, or pure carmine, by ammonia, the dichromate of lead by hydrochloric acid, and estimating the vermilion left insoluble. Alumina and oxide of tin, being necessary ingredients of commercial carmine, were not reckoned as adulterants. Other possible adulterating agents were looked for, but not detected. The most convenient quantity for examination was found to be one decigramme.

In determining the actual value of the respective specimens, number one was taken as the standard, the worth of the others being calculated from the per centage of carmine contained in them.

The difference in the cost of equal quantities of the samples was pointed out as somewhat remarkable, the poorest specimens generally costing most money; and even where reduction in quality was accompanied with reduction in price the former far outran the latter.

Finally, carmine should be completely soluble in solution of ammonia, and attention should be paid to the purity of tint and comparative depth of colour of the resulting solution.

A diagram, exhibiting the composition of the several samples, was suspended in the theatre; the following table is an abridgement of it:—

	Carmine.	Alumina.	Vermilion.	Chrome red.	Cost of 10 grains.	Actual Value.
I.	99·4	·6			5*d.*	5*d.*
II.	63·0	6·0	31·0		5*d.*	3½*d.*
III.	35·5	2·0		62·5	10*d.*	2*d.*
V.	76·7	3·6	19·7		10*d.*	4*d.*
VI.	46·6	3·4	50·0		3½*d.*	2½*d.*
VII.	26·8	2·0		71·2	3*d.*	1½*d.*
X.	28·3	6·0	65·7			
XII.	96·2	2·5			7*d.*	5*d.*
XIV.	23·0	trace	77·0		1*s.* 5*d.*	1½*d.*

The CHAIRMAN announced that owing to the Annual Meeting, and the Conversazione, there would be no Ordinary Meeting in May.

NOTICES OF BOOKS, PATENTS, &c.

On the Educational Uses of Museums. By Professor EDWARD FORBES. London: Longmans, 1853.

A MUSEUM really illustrative of chemical science has yet to be formed; the chemist may, however, learn what is to be avoided in forming one, and may also derive great advantage from a study of the collections devoted to other sciences. "An assemblage of curious things," is still often considered an adequate definition of what a museum is and should be. But the mere gathering together of things curious, rare, or beautiful (such are the objects supposed to be requisite), is but the first step in the formation of a museum. Classification must follow collection; while description, in whatever way conveyed, is also necessary before a museum can secure its full and real power of instruction. The founders or curators of many, if not of most museums, seem to think that their task is but to form, maintain, or increase a heterogeneous collection of objects. On this point the late Edward Forbes makes the following remarks, still, alas! too appropriate, in his admirable lecture "On the Educational uses of Museums," now before us, which we will take as the text for a few words on museums, and their relation to chemistry:—

"Unfortunately not a few country museums are little better than raree-shows. They contain an incongrous accumulation of things curious or supposed to be curious, heaped together in disorderly piles, or neatly spread out with ingenious disregard of their relations. The only label attached to nine specimens out of ten is, 'Presented by Mr. or Mrs. So-and-so;' the object of the presentation having been either to cherish a glow of generous self-satisfaction in the bosom of the donor, or to get rid — under the semblance of doing a good action — of rubbish that had once been prized, but latterly had stood in the way. Curiosities from the South Seas, relics worthless in themselves, deriving their interest from association with persons or localities, a few badly stuffed quadrupeds, rather more birds, a stuffed snake, a skinned alligator, part of an Egyptian mummy, Indian gods, a case or two of shells, the bivalves usually single and the univalves decorticated, a sea urchin without its spines, a few common corals, the fruit of a double cocoa-nut, some mixed antiquities, partly local, partly Etruscan, partly Roman and Egyptian, and a case of minerals and miscellaneous fossils, — such is the inventory and about the scientific order of their contents."

A long-established and somewhat extensive museum in the English lake district affords a striking instance of the entire absence even of an attempt at systematic arrangement. It requires a more profound attention than most visitors can be called upon to give, in order to discover the connection between the following objects arranged in the closest proximity in Crosthwaite's Keswick Museum, — a cluster of 55 nuts from Greystoke Park — chain armour of the time of Stephen — a stuffed char — slippers of rattlesnake skin — the helmet of an Irish dragoon! Again, what abstruse relation is there between a Chinese churn, a monster bamboo, the prow of a Russian ship ornamented with mica, the skin of a conger eel? But this museum, it will be said, is a private one, and in a remote and rural district. Let us visit, then, one of the most celebrated homes of learning.

What is the present state of the only Oxford museum that makes any attempt to illustrate the circle of the natural sciences? We cannot do better than quote the words of an Oxford guide-book; a guide-book which has the usual failings of such works, but which yet gives, in the extracts that follow, a fair idea of the collection known as the Ashmolean Museum. Let us premise that the specimens described are said to have been "arranged with the greatest accuracy by J.S. Duncan, D.C.L., according to the best recognised system." Now for the development of this admirable system: —

"Left of the entrance to the staircase are various skeletons and a collection of heads and feet of birds and quadrupeds: together with a fine collection of the heads of antelopes from the Cape of Good Hope, presented by H. Methuen, Esq.; also a model representing the nerves of the human face, by Mr. Paxton of Oxford; the head of a New Zealand chief who was killed in battle, &c. On the right of the room is a numerous assortment of the ingenious work of Asiatics, Africans, and other uncivilised nations.

After passing some Indian canoes arranged with great taste upon fragments of Egyptian sarcophagi, the visitor will find himself upon the staircase. Here is a varied collection of paintings: —

"A portrait of old Parr taken at the age of 152; an ancient and curious historical picture of the battle of Pavia; a drunkard; an idiot tormenting a cat; a gamester; a dead Christ, by Annibale Caracci (?); John Selden at an advanced age, and Louis XI. of France."

Another extract, completing the description of this interesting but miscellaneous collection (in which there are, it must not be forgotten, some almost priceless treasures), will be sufficient for the present purpose.

"On entering the second room, opposite the door is a large magnet supporting a weight of 160 lbs. To the left of the door, and at the west end, are lofty glass cases containing a splendid collection of stuffed birds. Near the first window is an ancient chair of the time of Henry VIII.; in the window-place is the head and foot of the dodo, a bird now extinct; also a curious rattle cut by a shepherd, and an ancient gag. Near the second window-place is a model of the Druidical monument at Stonehenge. Against the wall, opposite the entrance, are cases of reptiles and fish, in spirits and otherwise. In the fifth window-place, is a model in plaster of the field of Waterloo, representing the position of the contending armies when the Prussians approached; also a Babylonish brick. To the right of the window is a portrait of Mary Davis, on whose head grew two horns, which she shed twice (one of them being preserved in a glass case adjoining), and a variety of stuffed quadrupeds. Over these cases is a fine collection of the horns of ruminating animals."

The next curiosities are the following: —

"Christ bearing his cross, executed with the feathers of the humming bird; an ancient peg tankard (it having formerly been the custom for each person to drink from one peg to the other, and if he should drink more or less, to pay a fine); Burmese idols; fragments collected by Belzoni in the Egyptian catacombs; British and Roman relics from tumuli in Kent, Sussex, &c. and numerous other valuable curiosities."

The former curators of the Ashmolean Museum seem to have steadily kept in view the assertion of Plato: — "There can be no science of things perceived by the senses."

No doubt the New University Museum, under its present able curator, will present, when the collections are arranged, a very different aspect.

On what system have the contents of such museums as those we have noticed been arranged? Has the leading idea been that colour, that size, were the chief characteristics of nature? Regarding the specimens as curiosities, was it thought that ridiculous juxtaposition would enhance their curiousness? Why are badly stuffed animals so generally preferred to carefully articulated skeletons, the study of which would prove so much more instructive? The shabby rhinoceros and the dilapidated giraffe met with in so many museums are certainly of very slight educational value.

But it will no doubt be urged, "How is it possible to arrange the miscellaneous objects which usually constitute such collections?" Let only a clear idea of one principle of arrangement be formed and retained, and a partial success will at all events be achieved: an accurate catalogue and full descriptive labels will aid in the accomplishment of this result. Let us recount briefly some of the principles on which the contents of museums may be classified.

It might at first sight appear that the ideas of time and space would afford suitable grounds for the primary collocation of objects. But it will be found that historical succession and geographical distribution (for by these terms we must interpret the ideas of time and space respectively) will lead to awkward juxtapositions of wholly dissimilar objects, the relations of which will thus be distant and obscure. Still special purposes will sometimes justify and even require such arrangements, though generally the lesson to be taught would be difficult and the profit small. It needs no argument or illustration to prove that mere outward similarity, as a basis of classification, would involve numerous difficulties and absurdities. But it seems that a triple division into matter, force and life, will exhaust that aspect of the earth under which natural history and natural science present it to our attention. We may thus arrange our various collections in accordance with the three divisions of natural science — biology, physics, and chemistry. In each of these divisions certain theoretical or essential and also certain phenomenal sciences will be grouped: thus biology will include not only comparative anatomy, animal and vegetable physiology, but also descriptive zoology and botany, both recent and fossil. Moreover, all three divisions are linked together in many ways, which in a museum may be exhibited in the arrangement of the specimens illustrative of these connecting sciences.

To the comparative anatomists, physiologists, zoologists, botanists, palæontologists and physicists of the present time, may well be left the task of remodelling and perfecting the collections illustrative of their several sciences; the chemist, however, as yet has scarcely, if at all, employed the museum as a means of instruction in his department. In his lectures and his laboratory, to be sure, chemical apparatus and chemical products are constantly shown and described, but this is not in every respect equivalent to the uniform, intelligible, and patent classification which an extensive and well-arranged chemical museum might exhibit. Such a collection might serve many purposes, and might almost be made to describe itself. The enlightened chemist, taking warning from the failure, and learning from the success of other museums, will readily find a way of forming an instructive chemical collection. He will not, for instance, pursue the plan which appears to have been adopted in arranging the specimens presented to the Chemical Society of London, where the size of the bottles seems to have furnished the principle of classification. One might as well arrange a library into groups of folio, quarto, and octavo books, wholly regardless of their contents. But the specimens in a chemical museum should be so ordered and labelled as to illustrate the types, the notation, and the nomenclature of the science; while models of crystals and apparatus, together with diagrams and drawings, will serve to illustrate crystallography, chemical processes, and the arts dependant thereon, as well as to familiarise the student with chemical symbols, formulæ and reactions.

New or Improved Methods of Manufacturing a certain Metallic Compound or Alloy. Robert Mushet.

We have already noticed Mr. Mushet's patent for producing alloys of iron with tungsten or tungsten and manganese. The present patent is merely for puddling the alloy as prepared by the former process, and so rendering it malleable. He follows the common process for puddling, and states that the alloy so produced and puddled is denser and harder than ordinary iron.

Improvements in the Treatment of Iron. John Prentice Farrar.

This patent is for treating iron, while molten, with cyanogen or sal-ammoniac, which (he says) he finds to be "highly beneficial and successful in purifying cast iron, and in increasing the strength thereof."

As the patentee uses a pound and a half of prussiate of potash and two pounds and a half of sal-ammoniac to the ton of ore, or one and a half pounds of each of them to the ton of pig iron in the cupola, or to one ton of wrought iron if melted in the crucible, we confess we are totally at a loss to see what advantage he can expect to derive.

"In some cases I introduce the before-named ingredient into the ladle before tapping molten iron from the furnace, and into which ladle it may be drawn. I thus derive the action of the gases arising from the ingredients." It is these gases he looks to as his purifying and strengthening media.

As for the prussiate it will yield a little carbon, which if added to pig iron will incontinently be removed in the next process. As to two or three pounds of sal-ammoniac in the state of vapour purifying a ton of iron, we do not hesitate to say that it is a gross delusion. Mr. Farrar dates from New York. *Verbum sap.*

CORRESPONDENCE.

Arsenic Crusts.

To the Editor of the Chemical News.

Sir,—While acknowledging the ingenious character of many of Dr. Guy's adaptations, as described in his paper read before the Society of Arts, I must altogether demur to the proposed employment of flat discs of glass for receiving arsenical crusts. Except with very high magnifying powers (which are rendered unnecessary by adopting a process which I shall presently describe) a glass tube of half an inch diameter offers equal facilities for examination under the microscope. Indeed, for small crystals, even a quarter inch objective (magnifying 500 diameters) can be so employed, with the slight drawback of needing some extra focussing. On the other hand the rapid sublimation required in Dr. Guy's method must involve the loss of part of the arsenical vapour at the mouth of the tube, which is only loosely covered by the flat glass, and another portion, being very dense, will remain in the tube itself, whilst that which reaches the disc will be deposited on it in a nearly amorphous condition. No wonder that such "mists" should frequently require objectives of one-eighth inch to develop any crystallic character, and even then a few imperfect triangular facets afford but unsatisfactory evidence of *octahedralism* when we consider what weighty issues are in a measure dependent on the making out that feature. It is, however, in the power of the operator to obtain crystals of arsenious acid as perfect as he can those of alum an inch or two in diameter, and by acting on the same principle, namely, by obtaining a very gradual formation during slow cooling. The following is the *modus operandi*, as described in Table I. of my "Compendium of Qualitative Analysis." Drive the substance entirely off the lower half of the tube, which is made very hot by waving it about in the flame. Then re-vaporise the sublimate, holding the tube (which should be closed by a loosely-fitting cork) as upright as possible. The dense vapour sinks to the bottom, and will give large and regular crystals as the glass slowly cools. These crystals glitter in the sun like diamonds, and exhibit the same play of colours; they are from one one-hundred-and-fiftieth to one two-hundredth of an inch in diameter, and under an inch objective form specimens for the micro-crystallographer. Here and there we find octahedra absolutely perfect, but they are more frequently truncated; all the angles, however, being beautifully sharp. The majority are transparent, but some are only translucent, or even opaque. By reflected light (using a bulls eye condenser) they appear, in consequence of their adamantine lustre, like diamonds lying in high relief on a black ground; but their complete shape is most strikingly displayed by a combination of strong reflected and feebler transmitted rays of various degrees of obliquity. A tube of half an inch diameter, under a one-inch objective, presents nearly the entire field in focus, and the perfect crystals appear from one-half to three-quarters of an inch in diameter.

As regards the statement that arsenious acid sometimes assumes the cubic form, I would venture to suggest that Dr. Guy may possibly have been deceived by a hasty examination. An octahedron, if opaque and seen only by transmitted light, often appears a cube, since, when viewed perpendicularly to either axis, its section or outline is square. I may mention as a parallel case that I have obtained crystals of hydrate of calorine full a tenth of an inch in diameter which, for the most part, seemed to be perfect rhombs (the angles were 110° and 70°), but a closer observation convinced me that Faraday's description of them as "acute flattened octohedra with three unequal axes" (*i. e.* rhombic octahedra) was really correct. Such misapprehensions are very likely to occur under high magnifying powers.

I will describe an actual experiment which will show that my method is applicable to minute quantities as Dr. Guy's, while it is far more conclusive in its results. Dr. Guy states that a thousandth of a grain of arsenious acid yielded on sublimation a "circular mist consisting of brilliant detached points distributed evenly over the surface (of a disc) and easily resolved into octahedra under *an eighth* power of the microscope." By way of comparison I accurately weighed out a grain of pure arsenious acid on a balance sensible to the thousandth of a grain. I dissolved this in water, and make up to a known bulk. By means of a graduated pipette I took a thousandth part of this, containing of course a thousandth of a grain of arsenious acid, and evaporated it to dryness on a bit of curved glass. The latter, with the slight residue adhering to it, was then cut up and placed in a corked tube, four inches long by four-tenths of an inch in diameter. On igniting the fragments, a feeble sublimate appeared halfway up the tube, which, under a quarter-inch objective, was seen to consist of granules, evidently crystalline, but of indeterminable shape, and not more than one ten-thousandth of an inch in size. Re-sublimed by my method, these gave a few crystals, which were sought out by the inch objective, and then examined under the quarter-inch. They were beautifully perfect in shape, and about one twelve-hundredth of an inch in diameter. This alone would yield the strongest presumptive evidence of the nature of the substance in question, but I can by no means agree with one of the speakers at the meeting (Dr. Thudichum), who considered that we might afford to neglect applying the liquid tests to a solution of the sublimate. Each reaction must stand for what it is worth, but the concurrence of many furnishes proof the most irrefragable. The above quantity seems to be about the smallest that would yield any definite result in a tube of the size named; but unless much more than a thousandth of a grain of arsenious acid were obtained by Reinch's test, I, for one, should be extremely loath to assert that it had been criminally administered. Indeed I fear that the detection of this particular poison has reached an almost dangerous degree of delicacy, for we live surrounded by means of unconsciously absorbing traces of arsenic. We breathe arsenicated dust from the green flock papers on our walls; arsenical

papier mouré lies soaking on dishes afterwards used for culinary purposes; arsenic is contained in glazed green papers which are often employed for wrapping cocoa and other articles of food, and confectioners supply it wholesale in their cake ornaments. The very drugs prescribed for our relief, especially the compounds of bismuth, are tainted with arsenic, and it has even been detected in carbonate of soda. Nay more, even our vegetable food, as Professor Davy has lately pointed out, may be contaminated with arsenic derived from superphosphate manure, and there is probably no drinking water containing iron without a trace of arsenic as well. Now metals are remarkably prone to become localised in particular organs; the "dropped joints" of painters are found to contain lead permanently combined with the tissue, and a course of iodide of potassium will bring off abundance of mercury by the urine years after its administration. It would appear by no means improbable that traces of arsenic occasionally introduced into the system may be stored up in like manner (especially in the liver), till in the course of years the amount becomes appreciable. Many aquatic plants contain much iodine, all gradually absorbed from the water in which they live, though it cannot be detected therein from the minuteness of its quantity; the vegetable tissue, however, accumulates it and retains it persistently. So may it be with arsenic in the human body; and I think toxicologists should pause before affirming that it had been criminally administered unless a proportionate amount of the poison is found.

I am, &c. FREDERICK W. GRIFFIN, Ph. D.

Improvements in the Manufacture of Steel and Wrought Iron.

To the Editor of the CHEMICAL NEWS.

SIR,—I have observed in the CHEMICAL NEWS (p. 203) a notice of my patent for Improvements in the Manufacture of Steel and Wrought Iron, which ends with an inquiry respecting the breaking up of the metal on the floor of the refining chamber. To obviate this difficulty, which is the chief objection to the process, I give the floor of the chamber a sufficient inclination from the cone on which the melted iron strikes to prevent its accumulating in thick plates or lumps. Cast iron moulds similar to those now in use may also be conveniently used. The process is now being carried out at the works of the Pembrokeshire Coal and Iron Company, and I hope shortly to be able to bring some of the iron, which will be found to possess very great tenacity and closeness of grain, before the notice of the public.—I am, &c.

W. H. NEVILL.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

On Hyponiobic Fluorides.—H. Rose describes some of these combinations.[1] The hydrate of hyponiobic acid easily dissolves in fuming hydrofluoric acid at the ordinary temperature. When the solution is evaporated to dryness, hydrofluoric acid is first disengaged, and then by further heating white vapours of the fluoride: there remains the hyponiobic acid, which is yellow while hot, but becomes white on cooling. When it is attempted to distil hyponiobic with hydrofluoric acid, the former is not volatilised; but if some concentrated sulphuric acid is added to the mixture, vapours of the hyponiobic fluoride are produced at the ordinary temperature, which decompose in water. Hyponiobic fluoride, like the niobic, combines with metallic fluorides, but the combination of these double salts could not be obtained with the hydrofluates of fluoride of sodium and potassium.

The fluoride of hyponiobium and potassium is obtained either in a crystalline powder, in scales or in needles. Dried at 100° C. it dissolves in a small quantity of warm water, but the solution becomes turbid after some minutes, and can only be made clear by the addition of some dilute sulphuric acid. When the excess of sulphuric acid is driven off, the sulphate of potash can be separated from the hyponiobic acid by means of water. The salt contains $2\,K\,Fl + Nb\,Fl_3$.

The fluoride of hyponiobium and sodium appears to contain

$$Na\,Fl + Nb\,Fl,$$

mixed with some hydrofluate of fluoride of sodium and some fluoride of sodium.

II. ORGANIC CHEMISTRY.

Gases in Milk.—Hoppe[2] has published a long account of the ingredients of milk, to which we shall return on another occasion: the following analyses of the gases in that fluid we extract now. The milk was drawn and the examination was made with all possible precautions, but the results obtained were very different. The milks contained from 3·2 to 3·4 per cent. at 38°C. and the composition was as follows:

	I.	II.
Carbonic acid	9·00	55·15
Oxygen	9·57	4·29
Nitrogen	81·43	40·56
	100·00	100·00

On Two New Series of Acids.—When monochloracetate of soda is boiled with water, it is converted into chloride of sodium and glycolic acid. Heintz endeavoured to form lactic acid by treating monochloracetic acid with methylate of soda. The reaction indicated by theory took place, but the acid formed differed from both lactic and sarcolactic acids, although it possessed the same composition. Heintz has named it *methoxucetic acid.*

The reaction which takes place is as follows:—

Monochloracetic acid.	Methylate of soda.	Methoxacetate of soda.	Wood spirit.

$$\overbrace{C_4H_3ClO_4}+2\overbrace{C_2H_3NaO_2}=\overbrace{C_4H_3(C_2H_3)NaO_4}+\overbrace{C_4H_4O_2}+NaCl.$$

On evaporating the aqueous solution of methoxacetate of soda with some sulphate of zinc, and exhausting the residue with alcohol, methoxacetate of zinc is dissolved. This latter salt crystallises from the aqueous solution in large and beautiful crystals, which contain

$$C_6H_5O_5.ZnO + 2HO.$$

The solution of this salt decomposed by sulphuretted hydrogen, and submitted to distillation, gives at 198°C. methoxacetic acid in the form of a colourless acid liquid, with a smell like acetic acid. The author expresses the composition of the acid by the formula $\left.\begin{matrix}C_6H_5O_4\\H\end{matrix}\right\}O_2$.

Ethylate of soda acts violently on monochloracetic acid: the products of the reaction are chloride of sodium, and the soda salt of a new acid homologous with the last, which Heintz calls *ethoxacetic acid.* Its formula is $C_8H_8O_6$.

In the same way *amoxacetic* and *phenoxacetic acids* are formed by the action of *amylate* and *phenylate* of soda on monochloracetic acid.

When the soda salts of organic acids are heated with monochloracetic acid, chloride of sodium is formed, and new organic products which the author proposes to study.[3]

Combustibility of Tobacco.—Smokers know that there is a great difference in the combustibility of various tobaccos, but have not troubled themselves about the reason why. M. Schlœsing, chemist to the Imperial Tobacco Manufactory, has however occupied himself with the question, and has come to the following conclusions: 1. That the ashes of a combustible tobacco always contain carbonate of potash (tobacco never contains soda) in proportion to its combustibility. 2. That the ashes of an incombustible tobacco do not contain carbonate of potash. 3. That an incombustible tobacco may be made combustible if an organic salt, such as malate, citrate, oxalate or tartrate, be added to it. And 4. That a combustible tobacco may be made incombustible by adding to it a sulphate or chloride of calcium, magnesia, or ammonia. The carbonate of potash, however, cannot be the cause of the combustibility, inasmuch as it does not pre-exist in the plant but is a product of combustion. The cause must be

[3] *Monatsbericht d' Acad. der Wissenschaften zu Berlin*, Aug. 1859, p. 554.

looked for in the organic compounds of potash, the incineration of which furnishes the carbonate. In a future communication the author intends to give some information which will tend to improve the culture of tobacco.[4]

The Alcoholic Fermentation.—M. Pasteur[5] publishes the beginning of a long essay on the alcoholic fermentation, in which he shows that glycerine and succinic acid are constant products of the alcoholic fermentation, that the elements of these bodies are obtained from the sugar and not from the yeast: that glycerine, succinic acid, alcohol and carbonic acid, are not the only products; and that lactic acid is sometimes an accidental product. He then enters on the question what becomes of the yeast, and shows that the nitrogen of this body is never transformed into ammonia during the fermentation, and that when ammonia is added it disappears.

Houblonine.—A M. Ramont[6] has made a great discovery. He says that by making a decoction of hops in a close vessel, he has obtained an extract which he calls *houblonine*, and which he says contains all the active principles, aromatic, bitter, and astringent of the hop, by the help of which he expects to simplify the brewing of beer.

III. CHEMICAL ANALYSIS.

Removal of Arsenic from Sulphuric Acid.—Dr. Grüger[7] writes that arsenic is most easily removed from sulphuric acid by means of chloride of barium. Crystals of this salt should be added to the acid previously made hot.

SCIENTIFIC NOTES AND QUERIES.

Determination of the Amount of Alcohol in Wines and other Alcoholic Mixtures.—SIR,—In reply to your correspondent in No. 16 of the CHEMICAL NEWS, p. 192, I beg leave to say that I did not "set out with the assertion that the result obtained in the working of the example is erroneous." What I said was that if the rule given in No. 3 were followed it must give a false result: and I must say so still; for the correct result is obtained by following, not the rule given at p. 36, but a different rule, this, viz. from the sum of unity + the sp. gr. of the wine subtract the sp. gr. of the fluid after evaporation and made up with water. In the formula given by me at p. 108, $s_2 = 1 - 2\Delta$ is the sp. gr. of a volume v of alcohol and water. When another volume v of water is added to this the sp. gr. of the volume 2v will be $\frac{1+s_2}{2} = 1 - \Delta = 1 + w_1 - w_2$; and it is according to this formula that the example in No. 3 is worked, and *not according to the rule given in words*. The example was worked by some one who knew how to depart from the rule. But there are others who simply follow a rule laid down; such persons would *necessarily* obtain a false result by following the rule given in No. 3. For ± ·0127 is the only possible difference between 1·0080 and 0·9953: by no operation direct or "reverse" can 0·9873 be the difference.—*E. C.*

Valuation of Stannate of Soda.—SIR,—Would any of your numerous correspondents be so kind as to favour me with a simple and expeditious method, by means of which the amount of soluble oxide of tin in commercial stannate of soda could be determined volumetrically.—*Chemicus.*

MISCELLANEOUS.

Liebig's Soup for Invalids.—Take half a pound of newly killed beef or fowl, chop it fine, add 1½lb. of distilled water, with four drops of pure muriatic acid, and 34 to 67 grains of common salt, and stir well together. After an hour the whole is to be thrown on a conical hair sieve, and the fluid allowed to flow through without any pressure. The first thick portions which pass through are to be returned to the sieve, until the fluid runs off quite clear. Half a pound of distilled water is to be poured in small portions at a time on the flesh residue in the sieve. There will be obtained in this way about a pound of fluid (cold extract of flesh), of a red colour, and having a pleasant taste of soup. The invalid is allowed to take it cold, a cupful at time at pleasure. It must not be heated, as it becomes muddy by heat, and deposits a thick coagulum of albumen and colouring matter of blood. In soup prepared in the usual way by boiling, all those constituents of flesh are wanting which are necessary for the formation of blood albumen; and the yolk of egg which is added is poor in those substances, for it contains in all 82½ per cent. of water and fat, and only 17½ per cent. of a substance the same or very similar to albumen of egg. But whether it is equal in its power of nutrition to the albumen of flesh, is at least doubtful from the experiments of Magendie. Besides the albumen of flesh, the new soup contains a certain quantity of colouring matter of blood, and with it a much larger quantity of the necessary iron for the formation of the blood corpuscles, and finally the muriatic acid to assist digestion. A great obstacle to the use of this soup in summer is its liability to change in warm weather. It enters into fermentation like sugar with yeast, but without acquiring a bad odour. What may be the substance which gives rise to this fermentation is a question well worthy of being investigated. The extraction of the flesh must consequently be made with very cold water, and in a cool place. Iced water, and external cooling with ice, completely remove this difficulty. But the most important point to be attended to, is to employ meat quite recently killed, and not several days old.

Adulteration in America.—Dr. Hiram Cox, the Cincinnati inspector, has published many deeply interesting facts of his experience in testing liquors sold in that city. In 700 inspections of stores and lots of liquors of every variety, he found that 90 per cent. were impregnated with the most pernicious and poisonous ingredients. Nineteen young men, all sons of respectable citizens, were killed outright by only three months drinking of these poisoned liquors. Many older men, who were only moderate drinkers, died within the same period of delirium tremens, brought on in one quarter the time usual, even with confirmed drunkards, by drinking this same poison. Of 400 insane patients, he found that two thirds had lost their reason from that cause. Many of them were boys under age. One boy of seventeen was made insane by the poison from being drunk only once. Seeing two men drinking in a grog shop, and that the whisky was so strong that it actually caused tears to flow from the eyes of one of them, the doctor obtained some of it and applied his tests. He found it to contain only 17 per cent. of alcohol, when it should have contained 40, and that the difference was supplied by sulphuric acid, red pepper, caustic potassa, and strychnine. A pint of this liquor contained enough poison to kill the strongest man. The man who had manufactured it had grown wealthy by producing it.

ANSWERS TO CORRESPONDENTS.

*** In publishing letters from our correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

S. C.—When a tincture is made with Egyptian and Turkey opium together, they should first be dissolved in boiling water, and the rectified spirit added when the solution is cold. The tincture can then be obtained bright. Generally a tincture made with Egyptian opium will not filter bright, but now and then a sample is met with which will.

B. G.—We do not think it necessary to teach our readers the rudiments of chemical analysis. There are several small works on analysis which you can buy. Fresenius or Noad is often to be met with cheap on London bookstalls.

W. D.—1. By the slow combustion of phosphorus (*See* CHEMICAL NEWS, No. 10.—2. 40 cells are required to show the light well.—3. The details of the process will be found in the specification of the patent.—4. Mix two equivalents of the ferrocyanide with 5 eq. of nitric acid diluted with an equal bulk of water. When dissolved, transfer the solution to a large flask and heat over a water-bath. When it gives only a dark green or slate coloured precipitate with ferrous salts, remove from the fire and leave the solution to crystallise. Separate the mother liquor, and neutralise with carbonate of potash. The liquid then contains only the nitro-prussiate and nitrate of potash. The nitrate crystallises out first, and the remaining liquid on further evaporation gives crystals of the nitro-prussiate.—5. Not inconvenient: but would require at first a little more thought.

Cymro.—1. We cannot.—2. Hassall's *Adulterations Detected*, &c.

W. G.—1. We do not know Susquehanna root. It is a mythical remedy of some country quacks.—2. We cannot answer the question.—3. *a* should be

$$4\,(KO\,ClO_5) + 12\,HCl = 4\,KCl + 12\,HO + 3\,ClO_4 + 9\,Cl\,;$$

and *b*

$$3\,(KO.ClO_5) + 2\,(HO\,SO_3) = 2\,(KO.SO_3) + 2\,HCl + KOClO_7 + 2\,ClO_4.$$

—4. The mercury ought not to separate, but it is rare to find a sample in which it does not.—5. Probably yes, if the vine disease should increase.

A College Chum.—It is probably a mixture of several things (the composition of which will depend upon the degree of purity of the original benzole), and some undecomposed nitro-benzole.

THE CHEMICAL NEWS.

Vol. I. No. 21. — April 28, 1860.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Action of Chlorine and Iodine on the Oxide and Salts of Silver, by M. Alfred Naquet.[1]

1. Action of Chlorine on Nitrate of Silver.—The author passed chlorine into a solution of nitrate of silver until the liquid smelt strongly of that gas, and then filtered it through asbestos. The filtered liquor was coloured yellow by some free chlorine, and did not contain the least trace of silver, which was proved by testing with hydrochloric acid and sulphuretted hydrogen. It was now left in a vacuum for 20 hours, at the end of which time it had lost all colour and did not precipitate nitrate of silver, showing that the free chlorine had been removed. It smelt strongly of hypochlorous acid however, and decolorised indigo. As the absence of colour excluded the possibility of the presence of chlorous acid, that of hypochlorous acid could not be doubted.

It remained to be seen whether chloric, or even perchloric acid, was not produced at the same time. For that the author divided the liquid into two parts. The first was saturated with potash, then placed in a water bath, and a current of carbonic acid passed through it for several hours. At the end of the operation, the gas, which at first smelt strongly of hypochlorous acid after being passed through the liquor, had lost all odour. The liquid no longer bleached indigo; and as sulphurous acid did not restore the bleaching property, it was concluded that the liquid contained no trace of chlorate.

The second portion of the liquor was similarly treated with carbonic acid, then evaporated to dryness, and the residue calcined; this, redissolved in water, was not precipitated by nitrate of silver in the presence of nitric acid. The original solution, therefore, did not contain perchloric acid.

From this it appears that the action of chlorine on a solution of nitrate of silver, produces chloride of silver and free hypochlorous acid. Perhaps chloric acid would be formed if the solutions were more concentrated.

2. Action of Iodine on the Nitrate and Oxide of Silver.—The author first treated an excess of iodine with nitrate of silver in the cold. The insoluble deposit was separated by filtration from the solution, which was then digested with oxide of silver, and the precipitate now formed was added to the first. The united precipitates were then treated with alcohol, to remove the free iodine, and afterwards boiled with a solution of pure potash. After boiling a short time, the liquid was filtered. The filtrate was coloured blue by the simultaneous action of starch paste and sulphurous acid, but was not changed when chlorine was substituted for sulphurous acid. On being left to cool, it deposited a slightly soluble salt, which possessed the characters of iodate of potash, but which the author did not analyse.

[1] *Répert. de Chim.* 1860, p. 126.]

The deposit left after the action of the potash was formed of a mixture of oxide and iodide of silver, which were separated by means of weak nitric acid.

The first experiment went to prove that in the action of iodine on nitrate of silver (or, which comes to the same thing, on oxide of silver) iodic acid and iodide of silver are produced. Nevertheless, as the presence of iodic acid was only revealed by boiling with potash, it might be supposed that a less oxygenated compound of iodine was first formed which was decomposed by the reagent. The author, therefore, recommenced his experiments as follows: —

He first heated a mixture of iodine and oxide of silver mixed with water, to boiling, these two bodies having but a feeble action on each other in the cold. When the reaction was finished the solution was filtered. The filtrate was acid, and coloured yellow by free iodine, which the excess of acid prevented from colouring starch blue. This colouration took place on the addition of sulphurous acid, but not on the addition of chlorine. Another portion of the filtrate evaporated in a vacuum, left a white hygrometric mass which possessed all the reactions of iodic acid.

If the first experiments were correct, the precipitate ought to contain iodate of silver. Fearing that in the former case the iodic acid might have been formed by the action of the potash on some iodine which had escaped the alcohol, another proceeding was adopted. The author boiled the precipitate with an aqueous solution of iodide of potassium, and then found, by means of sulphurous acid and starch, that the filtered solution contained an iodate.

By the action of iodine on oxide of silver, there is formed, then, iodide of silver and iodic acid. If the oxide is in excess, all the acid is in the form of iodate of silver; if, on the contrary, iodine is in excess, a part of the acid is found free, while the rest is combined with the oxide of silver.

To account for the production of free iodic acid, the author treated iodate of silver with iodine, and found that under these circumstances iodic acid was set free.

Some phenomena which the author observed led him to examine the action of nitric acid with four equivalents of water on the iodide and iodate of silver, and on a mixture of these two salts, as well as that of potash on the two first, and he discovered:

1. That iodide of silver is decomposed by boiling nitric acid, with the formation of nitrate of silver and the disengagement of iodine;

2. That the mixture of the iodide with the iodate, neither facilitates nor hinders the decomposition;

3. That the iodate of silver dissolves in boiling nitric acid without alteration;

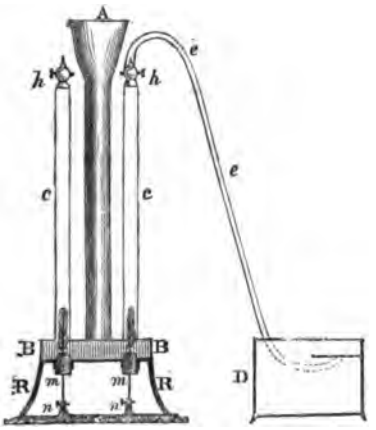
4. That caustic potash quickly decomposes iodate of silver even in the cold, forming iodate of potash and oxide of silver;

5. That iodide of silver is not acted on by potash in the cold, and only very slightly when the two are heated together.

On the Construction of a New Electrolytic Apparatus, by J. J. Coleman, *Lecturer on Chemical and Physical Science, Commercial College, Making Place, Halifax.*

Notwithstanding the numerous forms of apparatus already contrived for the purpose of decomposing water, by the agency of a voltaic current, the collection of the gases separately, and in sufficient quantity for experimental demonstration, is yet a rather troublesome operation. These considerations have induced the author to construct an instrument, the use of which is free from many objections attending the employment of the apparatus in common use, and as it has worked very satisfactorily, it is thought that the details of its construction may be deemed interesting to those concerned in this particular department of experimental science.

A simple inspection of the diagram will suffice to show the principle upon which the apparatus is constructed.



B B represents a closed chamber of glass; from its upper surface proceed three glass tubes. Two marked c c are of equal dimensions, and their upper apertures are furnished with stopcocks and jets, *h h*.

The other tube marked *a* is placed a little behind the two marked *c*, it is considerably wider, and is furnished with a funnel-like opening at the top. In the under plate of the closed chamber are two apertures *m m*, exactly beneath the tubes *c c*. These are furnished with corks, through which pass the electrodes, the conducting wire being attached to the battery by means of the binding screws *n n*. R R is a support for the whole.

In order to make use of the apparatus, water, acidulated with dilute acid, is poured into A (the stopcocks *h h* being open), until the tubes *c c* are exactly filled. The stopcocks being now turned, and connexion made with the battery, decomposition will take place, the evolved gases collecting in the tubes *c c*, an equivalent bulk of water being forced back into A.

If the apparatus is used for lecture demonstration, the hydrogen can be ignited and burnt at the jet without any trouble, and the usual test applied to the oxygen. The effect of lessening the size of the positive electrode is capable of being shown in a very interesting manner, as the ozone can be detected with the utmost ease by merely holding test paper over the jet as the gas escapes.

On the other hand, if it be desirable to transfer the gases to other vessels, the conducting tube *e* must be attached to the stopcock by means of a connector; the stopcock is opened, and dilute acid poured into A until the tube *e*, as well as *c*, are completely filled; the stopcock is then turned. When the gas has collected in *c*, it will only be necessary to open the stopcock and fill up A with water or dilute acid, and the gas will at once be transferred to the receiver in the pneumatic trough.

In the ordinary form of apparatus, the wetting of the hands with dilute acid cannot be avoided, which, to say the least, is not by any means pleasant, but, it will be observed, that with this instrument no such necessity occurs. Again, the little trouble required in its management, the ease with which the electrodes can be removed, altered, or replaced, the perfect control the manipulator has over the products, in whatever quantity they may be liberated, must be very obvious. Not only is it valuable for lecture demonstration, but also for volumetric determinations; the gases can be transferred by the method already detailed with the utmost accuracy. Finally, the instrument is well adapted for other electrolytic experiments than the decomposition of water, as the electrodes can easily be replaced or examined, and any gas evolved collected for experiment with the utmost ease.

A very interesting modification of the above apparatus can be constructed by substituting for the two tubes *c c* a single Volta's eudiometer, so as to enclose both electrodes; the mixed gases would then be collected ready for detonation; but, unless a stopcock were attached to the upper end of the eudiometer, the instrument would be rather awkward to fill.

PHARMACY, TOXICOLOGY, &c.

On some of the Chemical Re-actions of Strychnia, by T. G. Wormley, *M.D.*

(*Continued from page* 219.)

8. Bichloride of Platinum.—1. $\frac{1}{100}$, an immediate yellow amorphous ppt., soon becoming granular.

2. $\frac{1}{500}$, in a few moments an amorphous ppt., which soon becomes granular.

3. $\frac{1}{1000}$, in a few minutes the results are very good.

4. $\frac{1}{5000}$, if the solution be rubbed, small granules begin to appear in a few minutes, and soon the result is satisfactory.

9. Terchloride of Gold.—1. $\frac{1}{1000}$, gives a bright yellow amorphous ppt., which soon becomes partly granular; most of the granules float upon the surface of the drop. A portion of the ppt. collects into little yellow flakes.

2. $\frac{1}{5000}$, gives an almost immediate precipitate.

3. $\frac{1}{10000}$, gives very satisfactory results.

4. $\frac{1}{50000}$, at this degree of dilution the ppt. is still perceptible, but not satisfactory.

When the ppt. obtained from a solution containing $\frac{1}{1000}$ or less of its weight of strychnia is boiled, the ppt. will dissolve and give a yellow solution, from which it will again be deposited with little or no change upon becoming cool. If the solution contains more than $\frac{1}{1000}$ its weight, the ppt. will not entirely dissolve upon boiling; after cooling there will generally be a metallic gilding upon the sides of the tube. The ppt. produced from $\frac{1}{5000}$, or more dilute solutions will readily dissolve, without change of colour, upon the addition of a drop or two of potash solution; if then the solution be boiled it will become a fine purple colour, with sometimes a purple ppt. When the ppt. is from a stronger solution than above stated, it does not readily dissolve in potash, and when the mixture is boiled it yields a fine purple solution, with more or less of purple precipitate.

10. Chromate of Potash (Yellow).—1. $\frac{1}{100}$ gives an immediate yellow mass of crystals, soluble in 30 drops of strong acetic acid.

2. $\frac{1}{1000}$, begins to form in a few seconds, but they are not very abundant after standing 15 minutes.

3. $\frac{1}{5000}$, with the microscope a few prisms may be observed in 8 minutes, but to the naked eye no indication after 20 minutes.

11. Bichromate of Potash.—1. $\frac{1}{100}$, an immediate mass of brilliant yellow dendroidal crystals.

2. $\frac{1}{1000}$, in a few seconds much the same as 1.

3. $\frac{1}{5000}$, crystals began to form in a few seconds, in a few minutes they are abundant.

4. $\frac{1}{10000}$, in a few minutes beautiful octahedra appear, resembling those of oxalate of lime.

5. $\frac{1}{15000}$, by rubbing, the crystals are obvious with the microscope in a few minutes, and in several they can readily be seen with the eye.

The precipitate produced by this reagent is not so readily soluble in acetic acid, as that produced by the yellow chromate of potash.

12. Carbazotic Acid.—This, and the three following tests, we have formerly recommended in our lectures. The only specific account we have seen of any of them, is in the recent edition of Taylor *On Poisons*, in which the iodine test is suggested.

An alcoholic solution of carbazotic acid will produce with—

1. $\frac{1}{150}$ grain of strychnia an immediate yellow amorphous ppt., soon becoming tufts of a twig-like form.

2. $\frac{1}{1000}$, almost immediately a ppt., soon becoming same as 1.

3. $\frac{1}{5000}$, by rubbing a few seconds, a copious deposit of granules.

4. $\frac{1}{10000}$, in about a minute much the same as 3.

5. $\frac{1}{20000}$, in a few minutes small granules are very obvious.

13. Chloride of Palladium.—1. $\frac{1}{100}$, an immediate dirty white ppt., soluble in acetic acid, insoluble by boiling.

2. $\frac{1}{1000}$, an immediate yellow precipitate.

3. $\frac{1}{5000}$, in a few seconds the ppt. is perceptible, and soon becomes pretty good.

4. $\frac{1}{10000}$, after rubbing for several minutes a few granules can be observed with the microscope.

14. Iodine.—Of the various tests recommended for strychnia, this is the most delicate. It was applied in the following experiments, by dissolving three grains of iodide of potassium in one fluid drachm of water, and then adding one grain of iodine.

1. $\frac{1}{1000}$, immediately a copious brownish yellow amorphous ppt., soluble in alcohol and ether, but only soluble in large excess of acetic acid. The ppt. partially dissolves in a few drops of potash solution, but is immediately replaced by a dirty white precipitate.

2. $\frac{1}{5000}$, a yellowish ppt., soluble in potash, and replaced by a dirty white precipitate.

3. $\frac{1}{10000}$, the precipitate dissolved in potash gives a faint white precipitate.

4. $\frac{1}{15000}$, the ppt. is immediately produced, and soon collects into little yellow flakes.

5. $\frac{1}{20000}$, if the drop be touched with a small drop of the reagent upon the end of a glass rod, it gives immediately a very obvious yellow precipitate.

If a few drops of the last named solution be placed in a watch glass, and a drop of the test fluid be placed by its side and allowed to flow into the solution, as they meet yellow streaks can readily be observed, and the solution will become turbid.

15. Bromine.—This reagent was prepared by saturating a strong solution of hydrobromic acid with bromine.

1. $\frac{1}{1000}$, gives an immediate bright yellow amorphous ppt.

2. $\frac{1}{10000}$, a greenish yellow precipitate.

3. $\frac{1}{15000}$, a dirty yellow ppt., which after a time nearly all dissolves.

4. $\frac{1}{20000}$, the ppt. is perceptible, but soon dissolves.

16. Colour Test.—It is well known that if strychnia, or its salts, be dissolved in sulphuric acid, and then a small quantity of bichromate of potash, ferridcyanide of potassium, peroxide of lead, or of peroxide of manganese, be added, a series of colours are developed. This is known by the name of the colour test. We have succeeded best by placing the strychnia, or a drop of the solution evaporated to dryness, in a watch glass, and by its side a drop of strong sulphuric acid, into which a fragment of bichromate of potash was introduced, and stirred until it imparted a yellow colour; then by inclining the watch glass the coloured sulphuric acid was allowed to flow over the strychnia.

1. $\frac{1}{1000}$ grain of strychnia in one drop of water, gave in a majority of a number of experiments very satisfactory results, however, in some the reactions were just perceptible. In solutions stronger than the above the results were always very satisfactory.

2. $\frac{1}{2000}$, in many cases we failed to get any indication, in others there was a faint trace of colour, which very rapidly disappeared. In no instance was there such a reaction as should be sufficient for medico-legal purposes.

3. $\frac{1}{1000}$ of a grain, dry, will always give a fine reaction; by allowing the acid to flow upon a portion of the deposit at a time, several indications may be obtained from the same deposit.

4. $\frac{1}{2000}$, dry, in a majority of instances the results were very good; in some, however, they were very faint. The success of the experiment depends much on the character of the deposit left by evaporating the solution to dryness; sometimes the principal part of it is in the form of a ring, which, when examined with the microscope, consists of well-defined crystals; at others, the deposit is a confused mass distributed over the space occupied by the drop. In the latter case the result will not be nearly so satisfactory as in the former.

5. $\frac{1}{3000}$, in a number of cases manipulated differently, the majority gave no indication; some few a slight trace, but in no instance was the reaction satisfactory.

As the colour test is relied upon, perhaps, more than any other for medico-legal purposes, it is important to remember that it is interfered with by the presence of morphia. When *one part of strychnia* is mixed with—

1. One part of morphia, it gives very good results. The colours, however, are not so bright as with strychnia alone.

2. 1½ of morphia. If a small quantity of this mixture is used the reaction is very good, but in a larger quantity the reaction is just perceptible.

3. 2 of morphia. A small quantity of this mixture will give a pretty good reaction; $\frac{1}{50}$th grain gives but a mere trace.

4. 3 of morphia. A very small quantity of this mixture will give but little indication, and a larger quantity gives no reaction indicative of the presence of strychnia.

17. Physiological Test.—We are indebted to Marshall Hall for this test. It consists in administering strychnia to frogs, by which they are rendered violently tetanic; he recommended the frogs to be placed in a solution of the poison. Dr. Harley proposes to inject

the liquid into the thoracic or abdominal cavity of the frog.

In the following experiments a small portion of the strychnia solution—from 1¼ to 2 grains of fluid—was taken up by a pipette, the end of which was then introduced into the stomach of the animal, and the solution dislodged by blowing through the tube. The frogs were then placed under an open glass receiver. The species used was the *Rana Halecina.—Kalm.* From experiments made upon more than one hundred individuals, we are led to believe that this species is more sensitive to the effects of strychnia than any of the other several species found in this locality; however the difference observed may have been due to some other cause than difference of species. The weight of the frogs used in the experiments detailed below, varied from 18 to 45 grains.

1. When a solution holding $\frac{1}{100}$th its weight of strychnia was used, the animals immediately became rigid, with violent tetanic spasms, and died, on an average, in 8 minutes.

2. When a $\frac{1}{1000}$ solution was used, the symptoms usually began in about three or four minutes.

3. $\frac{1}{5000}$ solution: the symptoms appeared in some in ten minutes, in others they were delayed as long as 24 minutes.

4. $\frac{1}{10000}$th solution; of 22 frogs used, in 17 of them the symptoms appeared in from 27 to 45 minutes; in the other five there were no unequivocal symptoms; there was, however, very great prostration, and some slight tetanic movements.

5. $\frac{1}{20000}$th solution; of 10 small individuals used, eight were seized in 45 minutes, the others did not show unequivocal tetanic spasms.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY, *Thursday*, 19 *April* 1860.

R. Warrington, *Esq. in the Chair.*

Messrs. M. J. Stark, J. A. R. Newlands, J. McDonnell, C. E. Long, and F. Sutton were elected fellows.

Messrs. Perkin and Duppa read a paper *On the Artificial Production of Tartaric Acid.* The authors first attempted to procure bibromosuccinic acid by acting on succinic acid with bromine. This method proving unsatisfactory, they acted upon the chloride of succinyl with bromine, in sealed tubes heated to 120–30° C., whereby they procured the chloride of bibromosuccinyle, which by decomposition with water yielded bibromosuccinic acid, which acid after purification was analysed. It is a crystalline body, scarcely soluble in cold, readily soluble in hot water, very soluble in alcohol, still more so in ether. It is decomposed by heat, with production of hydrobromic acid. It is a bibasic acid, forming acid and neutral salts, several of which were examined. The neutral bibromosuccinate of silver when boiled with water underwent decomposition, with formation of bromide of silver. On filtering off the liquid and separating the small quantity of silver it contained by hydrochloric acid, refiltering, and evaporating to a syrup, which was placed *in vacuo* over oil of vitriol, crystals were formed, which by analysis and properties proved to be tartaric acid. The reaction was:

$$C_8H_2Br_2Ag_2O_8 + 2H_2O_2 = C_8H_6O_{12} + 2AgBr.$$

During the conversion of the bibromosuccinic acid, carbonic acid was constantly evolved, and a syrupy acid produced. This the authors believed to be pyruvic acid formed from tartaric acid by the loss of carbonic acid and water. Dr. Odling made some observations on the important services Messrs. Perkin and Duppa had rendered in this and their former papers, in extending and filling up the series of organic compounds consisting of carbon, hydrogen, and oxygen only, and drew on the black board tables of the acetic, propionic, and butyric families, thus:

C_2H_6O Alcohol.	C_2H_4O Aldehyd.	C_2H_2O
$C_2H_6O_2$ Glycol.	$C_2H_4O_2$ Acetic Acid.	$C_2H_2O_2$
	$C_2H_4O_3$ Glycolic Acid.	$C_2H_2O_3$ β Glyocylic Acid.
	$C_2H_4O_4$ α Glyoxylic Acid.	$C_2H_2O_4$ Oxalic Acid.
C_3H_8O Propylic Alcohol.	C_3H_6O Propionic Aldehyd.	C_3H_4O
$C_3H_8O_2$ Propylic Glycol.	$C_3H_6O_2$ Propionic Acid.	$C_3H_4O_2$
$C_3H_8O_3$ Glycerine.	$C_3H_6O_3$ Lactic Acid.	$C_3H_4O_3$ Pyruvic Acid.
	$C_3H_6O_4$ Glyceric Acid.	$C_3H_4O_4$ Malonic Acid.
		$C_3H_4O_5$ Tartronic Acid.
$C_4H_{10}O$ Butylic Alcohol.	C_4H_8O Butylic Aldehyd.	C_4H_6O
$C_4H_{10}O_2$ Butylic Glycol.	$C_4H_8O_2$ Butylic Acid.	$C_4H_6O_2$
	$C_4H_8O_3$ Butyrolactic Acid.	$C_4H_6O_3$
		$C_4H_6O_4$ Succinic Acid.
		$C_4H_6O_5$ Malic Acid.
		$C_4H_6O_6$ Tartaric Acid.

He also drew the following table showing the analogies subsisting between the succinic class of acids and the phosphoric acids.

$PH_3O_4 - H_2O = PHO_3$	
Phosphoric.	Metaphosphoric.
$C_4H_6O_4 - H_2O = C_4H_4O_3$	
Succinic.	Metasuccinic.
$C_4H_6O_5 - H_2O = C_4H_4O_4$	
Malic.	Maleic or Fumaric.
$C_4H_6O_6 - H_2O = C_4H_4O_5$	
Tartaric.	Meta-tartaric, or Tartaric-anhydride.

In the case of the metamalic and metatartric acids, there is no alteration of basicity; in the case of the metaphosphoric acid there is a difference which, however, may be only accidental, dependent upon the circumstance that phosphoric acid by losing an atom of water leaves only one atom of hydrogen, and consequently more than one atom of hydrogen cannot be replaced.

Mr. C. E. Long read a paper *On Crystallised Potassium and Sodium.* A piece of combustion tube, sealed at one end, and contracted in the middle, had introduced into the contracted portion a small funnel, resting only by its rim, and containing a wire gauze filter. After filling the tube with purified coal gas, lumps of thoroughly cleaned alkali metal were introduced into the upper part of the tube which, after continuing the supply of coal gas for some time longer

was ultimately sealed by the blowpipe. The metal was then partly melted, so as to expose a fresh surface to absorb any oxygen the tube might contain. After two or three days it was again melted and filtered through the gauge into the lower part of the tube which, by means of the blowpipe, was next separated at its contracted portion from the upper part of the tube containing the dross. The bright metal contained in the sealed tube was then melted and crystallised by suddenly pouring off during cooling the more liquid portions. The specimens have kept perfectly bright for eighteen months. Sodium has a most beautiful rose colour. It crystallises in quadratic octahedra, having apex angles of 50°. Potassium has a greenish blue colour, and crystallises in quadratic octahedra, havidg apex angles of 52°, and base angles of 76°.

Mr. D. Howard read a paper *On the History of Cinnamic Acid*. He found that crude cinnamic acid obtained from liquid storax contained a considerable proportion of cinnamic acid. By submitting purified cinnamic acid to distillation an oily product was obtained together with a small quantity only of unaltered cinnamic acid. The liquid product proved to be cinnamol, $C_{16}H_8$, boiling at 145° C. readily yielding the crystalline bibromide of cinnamol, being converted, at 200° C. into a glassy mass of metacinnamol, which at an increased temperature was reconverted into cinnamol. The cinnamol prepared from the distillation of cinnamic acid with excess of lime is perfectly free from benzol, but it contains a small quantity of a crystalline substance which proved to be identical in composition and properties with a compound named stilbene, obtained by Laurent from the destructive distillation of hydride of sulpho-benzoyl, $C_{14}H_6S_2$. Stilbene fuses at 125° C. and forms a crystalline bibromide, $C_{28}H_{12}Br_2$.

Messrs. Wanklyn and Buckheisen read a paper *On the Action of Sodium upon Iodide of Methyl*. Since sodium-methyl cannot be prepared by acting with sodium upon iodide of methyl, it was determined to examine the reaction to see whether methyl gas, which has never yet been obtained pure, could be prepared by this process. Iodide of methyl, ether, and sodium were heated together in sealed tubes to 100° C. The resulting gas after washing with water proved to have the following composition:—

C_4H_4 9·3 N 2·4 C_2H_4 65·0 C_2H_5 23·3

The next meeting of the Society will take place on Thursday, 3 May, when Dr. Gladstone will deliver a discourse *On Circular Polarisation*.

SOUTH KENSINGTON MUSEUM, 10 *April* 1860.

Lecture I. *On the Animal Products in the Museum, by* Ed. Lankester, *M.D., F.R.S.*

In pursuance of the object that I had in view on a former occasion when delivering a course of lectures on food, I come before you to night for the purpose of delivering a short course of lectures on the animal products used in the arts and manufactures. You are, perhaps, most of you acquainted with the fact that this museum is a representative of two departments which the Government of the country maintains for the purpose of the education of the great mass of the people of this country. It is called the Science and Art Department. With the Art Department I have little or nothing to do, and would merely here commend it to your earnest attention, and speak of it in terms of equal praise with the Department of Science, to which I am more immediately attached. Standing between our Art Museum and our Science Museum there is an additional museum, which has more particularly in view the teaching of the elements of the various branches of knowledge which are brought before the young. It is to this science collection which I wish more particularly to call your attention, and I would just say, in order that you may understand the position in which it stands in relation to the other collection, that it is only one part of a great whole. We collect together specimens of natural objects, as distinguished from objects of art, with which man's hand and mind have had much to do. With regard to the natural objects, they may be arranged together in a variety of ways, such as the natural history collection, a collection of all the varied forms of minerals, and also a collection of plants and of animals, as in the British Museum. They are there intended to illustrate, as it were, the varied forms of material objects which we find in the external world; in this museum, however, there is no attempt to illustrate so extensive an object, but the object kept in view is the illustration of the particular uses of minerals, of plants, and of animals; and, recently, within the last few years, there has arisen in this country and others a series of museums to illustrate the uses of external objects to man. It has been found that man's advancement upon the earth is entirely due to the way in which he uses these particular things, so as to apply them to his own wants. Hence we have economic or trade museums, representing, first, the raw materials of the mineral, vegetable, and animal kingdom, and then representing them in their manufactured condition, and passing through the various processes of their manufacture. Our own and other European governments have recognised the importance of these museums; thus we have in Jermyn Street a museum which contemplates not only exemplifying the geological history of Great Britain, but representing the various objects of the mineral kingdom used in the arts and manufactures. Then there are the great Botanical Gardens at Kew, where we find not only plants, but a large collection of the raw materials used by man for the various operations of the arts, and, to some extent, there is an attempt to represent there the manufacturing processes. In this institution we have the animal kingdom treated in the same way; we have a great collection of animal products which are used in the arts, and we have also collected specimens to illustrate the various processes which the raw materials undergo before they become fit for the use of man. It is my intention to show you what is the nature of the animal substances exhibited here, and what are the processes through which these substances pass before they are fit to be used by man for the various purposes of life.

But there is another view of the external world, to which I would draw your attention this evening, to show you the way we include the large department of which I have treated in the various courses of lectures. The external world supplies man with things which are not merely taken and used by him to supply an artificial want, such as wearing clothes, living in houses, and dining off plates, drinking tea out of cups and saucers, &c. but the world supplies him with things which he *must* take in common with the whole animal kingdom. There is the salt in the water and the various other saline substances which we eat; those are portions of the mineral kingdom which supply our natural wants. Then there are the materials of the vegetable kingdom, potatoes, cabbages, oats, wheat, rye, and other things which supply our wants in the vegetable kingdom. Then we take the animal, we roast and eat it, and in this way the animal kingdom supplies our wants, and I want you to see the parallelism. On the one hand nature supplies us with the food we take from day to day, as illustrated in our great museum. On the other hand, man is an artificial animal, dressing and using a variety of things sometimes from the vegetable, and sometimes from the animal kingdom, and it is the latter portion to which I wish to draw your attention in this and the ensuing lectures of this course.

Now I would just say a word or two with regard to those things. You see it is when man gets to know the properties of the materials of the external world that he uses these things. I do not know whether I can do better than illustrate it with the things I have before me. Who would think these little cocoons could ever be manufactured by man's ingenuity into the most highly prized articles of dress, giving a more pleasing and sightly appearance to the human form than any other substance? Thousands of our fellow-countrymen and countrywomen are employed upon and de-

pend entirely upon the employment to be derived from these little cocoons. Who would have thought all this would have depended, from the earliest times, upon the knowledge of the way to unwind the silk, to spin it, and to weave it? And then man having done this by his knowledge he is enabled to take a variety of substances from the mineral, the animal, and the vegetable kingdom, and stain the woven silk and give it a variety of colours, and so whilst he increases the beauty of the articles he increases the desire and the demand for them, and as man's intellect is employed in this occupation we may say it is by the intelligence of man as it is exhibited in the various manufactured articles that his civilisation may be indicated. You know when you go into a community of well dressed, well cared for people, that they are civilised, and what does that depend upon? It is not the ignorant man that is civilised; it is not the lazy man that is civilised. It can only occur in an intelligent, in an active and industrious community that you can find a civilised population—that civilisation can occur—and that gives us the greater encouragement to continue the study of these things. I want them to be studied a little more satisfactorily than they have been; it may be a little strange, but I believe my course of lectures here was the first attempt to systematise this study.

Before proceeding any further, I would just draw your attention to the distinction between animal and vegetable manufactures. It is curious that there should be so great a difference between the materials we employ from the animal and from the vegetable kingdom, and I will draw attention to the fact that the two sets of bodies are composed of different substances represented by the great primary materials of which plants and animals are more or less composed. Thus we find in plants, whether they are composed of vascular tissues, or of cells of this kind of form, that the greater part is composed of a hard substance called cellulose, or wood when it is formed into trunks and branches of trees. Now when we deal with the vegetable kingdom in our manufactures, we deal with this cellulose. When we deal with trees and cut them into boards, or when we take these delicate fibres and convert them into pocket-handkerchiefs and things of that sort, we deal with cellulose; and when we have worn all our cotton and our linen to rags, they are collected for the purposes of the paper-maker. The whole country is at this moment convulsed to know what we are to do for rags now we are going to take the duty off paper. There is an immense quantity of this cellulose in different parts of the world, in the forests of Asia, Africa, and America, and plenty in our own wildernesses, and it is only a question as to whether a man shall wear it first upon his back, or have it manufactured into paper at once. I believe the reduction of the paper duty will give the greatest incentive to the young chemists to pursue the subject and to make such discoveries and improvements in the art of paper-making, that the paper-manufacturer will be enabled to snap his fingers at rags. But when we examine the animal kingdom, we do not find any cellulose worth mentioning. Silk worms do not form it, nor is it to be found in the horns of cattle nor the hairs of animals, nor the feathers of birds, nor in any of the animal products used in the manufactures. We find there another thing called gelatine, or the substance used in making gelatine, always having the form of cells, but never having the properties of cellulose. Gelatine is soluble in hot water, while cellulose is not. Gelatine is known by its specific gravity being greater. Animal substances fall in water, but vegetable substances swim. Cellulose conducts heat with greater facility than gelatine, thus we are warmer in gelatine clothing than in cellulose. Animal substances are stronger. These, then, are some of the distinguishing features between substances that are manufactured from the vegetable kingdom and those which are manufactured from the animal kingdom. The artizan, the person who is working in these things, will do well to remember these facts, because out of some of them may arise important conclusions. Some of these dyes will not be taken up by the vegetable fabric. The dyes for cotton are not the dyes for the woollen or silk goods, and thus out of these matters arise the general facts with regard to animal and vegetable substances. Now looking at the animal kingdom, we see first that it supplies man with food, but we have nothing to do with that upon the present occasion. There is another application of animals with regard to civilised life. We use their strength or force. A man can lift a certain weight, and accordingly so many men equal a horse power, and so many horses make a steam engine power. This is a kind of muscular power which we constantly employ with horses, &c. in this country. That, however, is not what I want to treat of here, but the way in which their products are applied to the use of man. Take silk. Well, silk is woven into garments in a variety of ways, and used for purposes of textile fabrics. Then just as we use the solid portions of minerals and plants, so we use the solid portions of the animal, but, as the animal is more scarce, we do not use it for the same purposes; for instance, we do not build our houses with the animal kingdom; but there are certain portions of an animal, for instance, the skeleton, the bones, the horn, the hoof, the teeth, and a variety of other portions of animals, which are constantly used by manufacturers. Then, again, we find that the chemistry of the animal is of a different kind than the chemistry of the vegetable. You know that man is but a poor chemist in his laboratory as compared with a plant. Take a blade of wheat, exposed to the action of carbonic acid gas and ammonia; that little plant takes those elements in the most wonderful manner possible, and converts them to its own use in its laboratory, and lo! there is the cellulose, the oil, the starch, and the saccharine matter, and those little plants are doing this in every moment of our existence; whether we may be sleeping or waking, the laboratory of the plant is still employed for the use of man; the vegetable thus exercises an influence on the animal kingdom. The animal takes up the starch, and the sugar, the oil, the albumen, the fibrine, and the caseine, out of the plants, and then loosens the chemical affinities. An animal is more easily decomposed than a vegetable. If you doubt that, throw a log of wood and a dog into a stagnant pool; the dog, in a very few days, will become in such a state that you would not like to come near him, while the wood goes on for years and years before it becomes decomposed. But sometimes we arrest the change. There are these skins. We introduce tannic acid during their change, and they become leather. And there is the fatty matters of which we make soap. We take them while the chemical change is going on, and we employ them and turn them to a hundred uses in a variety of ways. Then there are certain things in the animal kingdom which come to us in the form of a disagreeable essence; there is the Muscovy cat, with its stinking scent, and we catch the animal, and import 10,000 ounces every year of that civet which we dislike so much; and then there is the musk ox and the deer, and ambergris, and other things which are used for perfumes. Then there are those dyes the cochineal and the lac insects yield. Then there are certain waste substances of animals, the Prussian blue, the purple, and the red, which we obtain from animal substances. Then there is a great quantity of things which are habitually thrown away as refuse. There are people who make buttons from bones and from the hoofs of cattle. When we come to study these things, we shall find that God has made no waste in the world at all. There is a maxim, "Waste not, want not," and we have wasted, and do waste, and in my last lecture of the present course I shall call attention to the waste in many things—in money thrown away in objects and in books.

Now to-night I will take up the subject of silk. You will see if you look at the whole animal kingdom how very few conquests man has made among the lower animals. Among the invertebrate animals—those animals without back bones—there are many that are useful to man. Sponge is an animal of the invertebrate group, and there is a variety of shell-fish yielding us mother-of-pearl. Then we come to

the various forms of articulate animals—crabs and lobsters; the bee yielding honey; the blistering fly yielding its secretion, which is valuable to man, under certain circumstances, and the leech, which is an article of trade among us. But I cannot say of all animals of the higher class that every part of them is at present useful. For instance, there is the hippopotamus: we cannot use every part of him; of his skin we could make leather, or we might boil him down and make him into jelly and eat him after dinner. But it is the insect tribe to which I wish to draw your attention to-night more particularly, in order to bring before you one of the most important of our arts and manufactures. This is the silkworm. Now, among the insects, of which you see a variety here, there are some that undergo changes of a remarkable kind, and some that undergo no change at all. Some produce eggs which produce creatures very much like their parents, while others produce creatures which are utterly unlike their parents. Take for instance the creatures to which the common moths and butterflies change. These lay eggs which produce larvæ which produce insects unlike their parents, who at last spin for themselves this grave or cocoon, and produce a thing which we call a chrysalis, where it lies for weeks, months, and sometimes even years; but at last the chrysalis bursts, and out comes the perfect insect — the butterfly or moth; and it is to these families that our silkworm belongs, to a family known to naturalists as the family of *bombycidæ*. This family has the habit of producing caterpillars which spin these kinds of cocoons or nests formed of a fibre which we know by the name of silk. It is not every species, however, of this family of *bombycidæ* from which we can obtain silk, although there are a large quantity of them that yield silk and fibre just in the same way as our common silkworm.

I have here a large number of specimens of silk obtained from other species of moth besides our common silkworm moth. That is an important point to recollect, for circumstances may occur by which we may obtain as large a supply as from the silkworm. There are difficulties in preserving the common silkworm moth, and if we could raise a coarse kind of moth for this purpose we should do the community a service. The more knowledge which those persons have who are engaged with these things, the more likely are they to make discoveries and introduce new sorts and kinds, and thus increase this serviceable produce. It has not been by ignorance or accident that man has discovered these things, but just as man has searched into nature he has been rewarded by discoveries, and if we expect to progress we must cultivate our minds, and bring them to bear on the practical arts of life. You see what splendid specimens of these creatures we have before us. Here is the *bombyx mori*, which produces all this silk and gives employment to a million of people in this country, and to millions in other parts of the world. And here is another moth having a peculiar mark on its wings. This moth deposits its eggs in the autumn, and these will hatch the next spring. Here is a bottle full of these eggs; they form little worms of this kind, which remain for six or eight weeks in this condition, increasing in size and eating more and more, until at last they become an exceedingly rapacious crew, devouring large quantities of the leaves upon which they live. They shed their skin four or five times before they begin to make the cocoon. Now this moth is called the *bombyx mori* because it feeds on the mulberry. There are two species of mulberry on which they are principally fed, the *morus alba* and the *morus nigra*. The *morus nigra* is the one that has been cultivated in Great Britain.

Unfortunately for us the silkworm always chooses to be hatched just before the leaves of the mulberry tree come out, so that we have a difficulty in feeding them. It does not seem that we have been able here or anywhere else to retard their coming out of their eggs. We are therefore compelled to substitute the lettuce and the dandelion, which both yield a very similar milky juice to the mulberry, and the creature will rather feed on these than die: but it is a fact that silkworms, fed in their early condition on lettuce leaves never thrive like those always fed upon mulberry leaves. Various attempts have been made to cultivate the silkworm in Great Britain. The black mulberry was introduced, and there are large orchards remaining which were planted centuries ago, but all attempts have failed owing to the worms hatching before the mulberry leaves come out. At the same time there is no reason why it should not thrive, as it succeeds in Russia and various parts of North America, and there are silks in this room from various parts of Great Britain. But the question is how can we obtain silk from our worms permanently without any of that liability to failure which has attended the cultivation of silkworms in this country? I recollect at various meetings of the British Association a lady appeared from time to time bringing specimens of silkworms and manufactured silk, endeavouring to show the gentlemen of the Association that it was possible to produce it here, and I recollect a very splendid piece of silk so produced, which was presented to her Majesty. But how did Mrs. Whitby of Southampton do this? Instead of cultivating the old black mulberry she cultivated another species—the *morus multicaulis*, having a leaf and fruit of a different kind, and not so eatable as the common black mulberry, but producing leaves much earlier than the *morus nigra*, and on this account she succeeded from year to year in producing good crops of silk of the best quality; according to her experience, therefore, it must not be decided that we cannot cultivate silk in this country, and I therefore recommend it to the study of all who are seeking for further means of obtaining money. There is no question that the time of females might be profitably employed in attending silkworms where they have nothing better to do. It is not a very profitable employment, still it only occupies a little time and attention, and when carried out it produces a clear gain. This is a fit subject for the philanthropist, as the cultivation of silkworms could be carried out in a cottage population. There is one great drawback, namely, the disease to which they are subject, the *muscardine*, and those who are at all engaged with manufactures of silk, in the sale of silk, or in the purchase of silk, well know how this has caused it to vary in price; how large quantities have been brought into the markets of Europe affected by the disease, and how within the last four years the greater part of European silk has been destroyed by this cause. Now the disease is of a kind that sometimes affects the human body. I have here a diagram of human hair affected by fungus, and diseases of the skin are produced by the same cause. Now a fungus of a very similar kind attacks the silkworm, and so entirely destroys the creature that when the time comes for it to form its cocoon it is utterly unable to do so, and the result is a failure in the crop. It has been found lately that feeding them with sugar prevents the disease, and it further appears that it is a disease produced by over crowding: those people who cultivate silkworms crowd them together in close places without a proper supply of pure and fresh air, and when a large supply of fresh air has been admitted to the cases in which they have been kept the disease has disappeared. There is no doubt that the disease will spread from one establishment to another, which shows that the same laws which prevail in the life of man prevail in the life of animals.

Now, there are several sorts of silkworms, just as we find among human beings that there are small ones and large ones, black ones and brown ones and white ones, so we find among these creatures a similar variety. In France there is the *sina* variety which produces white silk, and there is the Syrian which produces a very large cocoon. Then there is the *snowbee*, which is the small fine cocoon producing yellow silk, the most beautiful of the French silk. The *bombyx mori* is not found in our fields or hedges, for although occasionally a few eggs may fly out of the windows and get into our hedges, yet there is something in our climate which will not allow them to thrive. The year before last

was an exceedingly favourable summer for the production of these creatures in the open air, and a statement was made at the meeting of the British Association at Leeds by a gentleman that he had seen them feed and thrive in the open air. The worm is essentially a native of China. When our forefathers were naked savages understanding nothing at all about clothing, more than three-fourths of the population of China were clothed in silk. This is a lesson for us. The Chinese have not been a people of progress. They are almost a stereotyped edition of the human race. There they were 2000 years ago making silk in large quantities, and here they remain at the present day with no increased advantages, whilst we are continually progressing. They practise things merely as an art and know nothing of science. We see them the suppliers of the world not employing machinery in the manufacture, but doing just as they did 2000 years ago. The cultivation of silk seems to have been introduced into Hindostan and then to Europe at the time of the reign of emperor Justinian, and it was introduced into Constantinople by two Nestorian monks who were promised a reward if they would bring the worms which produced the silk. The Greeks and Romans knew something of silk, but none of them knew anything of its history. Aristotle thought it must have been produced by some worm like a caterpillar, and others thought it was the produce of plants, and certain Roman poets attributed it to flowers. In the sixth, seventh, eighth, and ninth centuries the silk known in Europe was entirely the produce of the Greeks. In the thirteenth century it was introduced into Sardinia where it found a home. In the fifteenth century it was introduced into France. In the sixteenth century it was introduced into England, but failed. Throughout all Europe silk was, until a very recent period, an article of excessive value. We find James the First, when the English ambassador went down to congratulate him, writing to the Earl of Marr to beg of him to lend his sovereign a pair of silken hose, so that his sovereign should not appear as a scullion. Nor had we been more successful in the manufacture of silk up to the seventeenth century. Although we attempted to grow it we failed, and we were in the same position as to our manufacture. Most of you have heard of the Revocation of the Edict of Nantes. This threw upon our shores 50,000 intelligent Frenchmen—many thanks to them—we are more indebted to them than at present people would like to confess. The Frenchmen established a silk manufactory in this country, and, although we could not rear the silkworm, we were able to manufacture silk, and now we have a great trade in the article. In 1820 we imported 371,000 lbs. In 1856 our importation amounted to nearly 7,000,000 lbs. In 1857 and 1858 it had amounted to 7,000,000. We have at this moment 300 silk manufactories with 2,000,000 of spindles going, and steam machinery of 4000 horse-power, independently of the hand weaving of Spitalfields. We have 15,000 men and 35,000 women employed in the manufacture. The quantity of silk that we use is something prodigious, and the entire quantity of this silk fibre is enormous. In Lyons, the manufacture has been carried on to a great extent, and a manufacturer of 1840 states that the silk consumed was 2,205,000 lbs. and that it was produced by four thousand millions of cocoons. The fibre of one cocoon measuring 1526 feet in length, so all the silk fibre used in one year in Lyons would measure six billions five hundred thousand millions of feet, a quantity sufficient to wind fifty-two thousand times round the circumference of the earth. So much for the manufacture of one town alone, and, of course, our home manufacture is much larger than that. The silk used in our manufactures is produced in various parts of the world. We obtain it from France, from Italy, from Sweden, from Russia, and especially from China, and now from Japan, and recently some of it came from America. After the creature has cast its skin five or six times it begins to form its cocoon; this is done by fixing the upper part of its body in such a way that it can reach around itself in every direction, and cover itself all over with the web which it spins, and at last form with it the hardened case which we call the cocoon. The way in which this is done is very curious, and I will draw your attention here to two large glands found on each side of the body of the silkworm. It is in those glands that the silk is secreted, running on to the front of the head and terminating in an organ called a spinnaret. On each side of the spinnaret are two glands, with a sticky matter very much like the silk itself, by which the produce of the two glands are made to adhere together and produce one fibre. This substance, when placed under the microscope, is found to have the appearance which you see here, it is transparent, and composed of a material called *seracine* by chemists. Silk fibre, of all substances that we know in nature, has the greatest strength for its size. So that you see it is in its great strength and fineness that its value consists. The way in which the silk is obtained for commercial purposes is in this way:—The creatures are allowed to feed upon the mulberry leaves in a large shallow basket, and in a short time they spin a cocoon. Several of these cocoons are taken and placed in vessels upon a table, and each end of silk is placed upon a reel, then, as the reel goes round, the silk is wound off, and thus formed into what we call hanks. It is in this condition when brought into the market. This is some from Canton. I believe some of the finest white silk is brought from China. I have here three specimens of American silk. The great drawback to American silk is that it is not uniform in its colour or quality; this is coffee-coloured, and this straw-coloured, and sometimes the American silks are almost green. I have here some specimens from Siam; these are not produced by the common *bombyx mori*. Here I have some from Russia. Even in Russia they can produce silk, and, as I said before, the reason that we cannot seems to be more from our want of management than anything else. Here is some of the fine silk from Japan, which has recently created a great sensation on account of its whiteness and strength, and it is now being used in a manufactory in Nottingham. This is silk from India, which retains its character for beautiful silk. Here is some Sicilian silk, and these are in the form in which they come into the market for the purpose of being manufactured. This is called *raw silk*. Now the raw silk is spun into what we call spun silk, and you have it twisted on these wheel spindles, and then afterwards rewound into the form of these small hanks, and it is in this way that the silk finds its way into the market in the form of silk yarn. The next process to which it is submitted is the process of dyeing. This spun silk is taken to the dyers, who submit it to a variety of colours. We have black, blue, and red dyes, of various shades; for black, galls and iron, with indigo, are the most frequent substances used for dyeing; but there is a great fraud in dying blacks. Silk is made to weigh 25 per cent. more when dyed than before, because it will take up a considerable quantity of sugar, which makes it assume a weightier and stouter appearance. You may easily ascertain the presence of sugar by the taste. The red colours are given by the agency of cochineal and lac, which colours are produced by these insects.

It would be out of my province to deal with the different manufactures, but I will call your attention to the variety of forms in which silk appears. We have the plain silks, the figured silks, and the beautiful surfaces called satins and satinettes. Then we have a very peculiar form of silk which is made into shawls; then silk lace, in the manufacture of which there are a thousand women employed in Nottingham. Then we have damasks and brocaded silks, and this poplin, which is composed of four parts of wool and one of silk, with gold pattern introduced into it. Here I have a manufacture from Japan, which is a mixture of hairs and silk. I have here some beautiful crapes presented to her Majesty, and by her Majesty presented to this museum. You can hardly imagine any thing more beautiful than these. Then I have here from Coventry a large variety of beautiful colours in ribbons.

During the manufacture of this silk into those various fabrics we have a large quantity of waste. We bring into this country a huge quantity of cocoons which have had their

silk reeled off, and they are called knubs and husks, which still yield silk used for coarser goods. I have here a quantity which is known as silk waste, which is also rewound and used into a variety of fabrics, so that no portion of the fibre is lost. Even in China after they have taken up the knubs and husks they take the chrysalises and make of them the most delicious mess with which they are acquainted as an article of diet. Strength is the appellation which is best applied to these little glands which form the silk, and I have here a substance manufactured from those little glands, and called silkworm gut, which makes an exceedingly strong and useful article for the purpose of the angler; and those who are fond of fresh-water fishing, such as for salmon and other kinds of fish, will appreciate this silkworm gut. So you see there is not any part of our little creature which is not more or less useful to man. I have no time to allude to the other insects on the table. I have spoken of the fact of the cochineal and lac producing dyes. This beautiful lac dye is produced by the creature which produces shellac, from which we make sealing wax, and this cochineal, which is valuable in medicine, produces crimson dyes. I now only bring forward the silkworm insect as a contribution of the invertebrate tribe of animals for the use of man and manufactures.

SOCIETY OF ARTS, 18 *April* 1860.

Thomas Winkworth, *Esq. Vice-President, in the Chair.*

The paper on *Indian Fibres*, announced for this meeting, was, owing to the indisposition of Dr. Forbes Watson, deferred *sine die*, and in lieu thereof Dr. R. H. Collyer delivered a discourse upon *Paper Material*, which we will tersely notice. The Author's opening remarks were devoted to the consideration of rags, and the ordinary methods of sorting, cleaning, bleaching, and pulping them; from which we learn that the loss incurred in these various processes, before the "finished article" is obtained, amounts to from 30 to 50 per cent on the weight of the rags employed.

Dr. Collyer then said: "I feel certain that rags are the most expensive material that can be used, nor can they produce paper equal in strength and durability to raw materials, when these are treated judiciously.

"I have a friend in the United States, who is now manufacturing some 30 tons of paper each week, the ingredient being principally wheat straw. The process consists in boiling it, under a pressure of 200 lbs. to the square inch, in a large spherical boiler of 14 feet in diameter. In this vessel he acts on some 10,000 lbs. of straw at one operation; it requires some four to five hours to get the whole to the heat of 320° Fahrenheit, which he continues for some 24 hours. He then removes the man-hole of the boiler and injects cold water, so as to be able to remove the material which is by this time compacted into a large glutinous mass, raw materials having a tendency to this agglutination when boiled in bulk. The object of these operations is to get rid of the silica and gluten. As a like process is used in England by other paper manufacturers, possibly with some modifications, my description will equally answer for other cases. High-pressure boiling involves a great sacrifice of fuel, nor is the object attained, for though the steam in the boiler acquires a very high temperature, the liquor itself is much lower.

"Now I ask any one who has seen these operations, can the alkaline liquor or the heat permeate a mass of material so matted and packed together? It is a well-known fact that this treatment is so unequal in its effects, that one batch or boil may turn out far better than the next, and also that those portions which come readily in contact with the alkaline liquor are sufficiently prepared, while those in the interior may be hardly acted on at all. The same objection exists in boiling rags. A paper maker of 40 years' experience told me the other day that frequently one portion of the rags was cooked when the rest was nearly in the same state as when first put into the boiler. This is particularly the case when over half a ton is boiled at a time. This statement has been corroborated by several of the most prominent makers, with whom I have lately been thrown into contact.

"Surely, then, if rags, which are free from those glutinous and gummy matters which invariably accompany raw materials, are subject to this difficulty of imperfect boiling when acted on in quantity, how much more must this be the case with the raw material?

"It is true that various contrivances have been adopted for obviating these inconveniences. Some have revolving boilers; others cause the apparatus to perform a semi-revolution, but no practical advantage is obtained. I now refer to raw substances, for with rags, in consequence of their freedom from gummy and glutinous matter, the revolving boiler saves both alkali and time, and ensures more uniform results.

"I now come, gentlemen, to that portion of my remarks in which I shall have to treat of processes which profess to remove all the obstacles attendant on the use of raw substances. I will show that what now requires from 8 to 14 hours to accomplish can be effected in 2, and that what now takes from 2 to 3 days may be perfectly well managed in 6 hours. Such a revolution in the preparation of paper material I did not in the least anticipate when I commenced my experiments five years since. If my observations do not appeal to your judgment as being based on correct chemical and mechanical principles, I must not expect to receive your assent or approbation. But I have done more than theorise on the matter, having erected machinery in my garden on a scale of sufficient magnitude to prove the process capable of being carried to any required extent. I should be happy to be visited by any of my audience or their friends, when I think it will be in my power to convince them that paper of every quality can be made quite independently of rags — at less than half the cost — of this fact I am certain. My process consists, first in passing the straw or other material between two rollers—running at different speeds—this produces a trituratory action, which in the case of straw, rubs out the knots and ears; these have always formed an insuperable obstacle in the case of straw, producing specks in the paper; the knot in particular is most difficult to bleach. So also is the ear. I am aware that those who make straw paper attempt to get rid of these by cutting the material into short lengths and winnowing them out, but it can easily be imagined how imperfectly this process must effect the object in view. The rollers also prepare the straw by opening it out into a partially fibrous state, so that it occupies only half the space it would take up in its natural condition, and besides the alkali has a more ready access to the fibre. In this condition it is packed in sieved trays, about one foot and a half in depth; these are placed in an apparatus to be operated on in detail, that is, each layer is supplied independently with a current of steam and alkaline liquors.

"In lieu of filling, for instance, with alkaline liquor, a vessel of 8 × 8 feet, having a capacity of about 400 square feet, or 2500 gallons, I only employ 500 gallons, of a strength of two degrees, or about three ounces of caustic alkali to the gallon—in fine, not over 1 cwt. of soda or potass to the ton of straw, whereas at present very few makers use less than from 4½ to 5 cwt. This is effected by using a reservoir at or near the bottom of the apparatus or vessel in which the materials are treated. From this reservoir the alkaline liquor is pumped to one above, from which the distribution takes place uniformly to each layer or stratum to be acted on. When perfectly saturated, the superheated steam acts under each stratum by an independent supply. The excess of alkaline liquor falls over the sides of the tray down to the bottom of the apparatus. In this manner a system of percolation and circulation is kept up for 40 minutes to one hour, when the spent liquor is drawn off, and the reservoir is refilled with fresh liquor, for it must be borne in mind that by this time the alkali, though not chemically neutralised, has lost the power of acting on the silica. I could enlarge, if time per-

mitted, on this topic, as illustrating one of the principal causes of failure in the modes now in use.

"The escape steam is not lost, for it enters tanks in which the alkaline liquor or water for washing is first boiled, for it is most important in the treatment of raw material that cold should not be brought in contact with it until the operation is complete, so far as the removal of gluten and silica is concerned. The paper now supposed to be made of straw, which in most cases is a mixture of cotton rags, is condemned as being brittle, harsh, and having an unpleasant rattle. These faults arise from the silex being only partially removed; this circumstance has caused a great prejudice against those papers.

"When the alkaline liquor has been drawn off, after one one hour and a half's treatment, the material is next washed, without removing it from the apparatus. This is effected by turning certain cocks which communicate with the lower reservoir, and admit the hot water. The straw is agitated by a simple contrivance, which causes every part to be repeatedly turned over. This washing process takes from 30 to 40 minutes; this is determined by the escape water running clear. The analogous operation occupies several hours at present, and is, after all, but imperfectly performed.

"The fibre is now clean, but to ensure a certain result I fill the reservoir with cold water slightly acidulated with hydrochloric acid, the cover of the apparatus having been previously removed. This cold solution is now mixed thoroughly with the material for about ten minutes; it is then washed away with extra cold water.

"I now come to that portion of my invention which is attended with the greatest economy of bleaching material.

"The solution of chloride of lime is completely mixed and incorporated with the straw, after which the superheated steam is let in at a pressure of from 30 to 40 lbs. It permeates the whole mass under treatment, the agitators being kept at work the same time.

"The bleaching is effected at once and more perfectly than if the material remained in a solution of chlorine for a whole day.

"This is easily understood, when the process or chemical change is analysed. It seems the chlorine combines with the hydrogen of the water, forming hydrochloric acid, while the oxygen attacks the vegetable fibre. The principal obstacle has been the deposit of the lime on the surface of the fibre, preventing in a great degree the further action of the bleaching process. By the employment of great heat, suddenly applied in the manner I have patented, the best and most uniform results may be relied on.

"Instead of washing out the acid formed, I prefer neutralising it by the addition of chalk or other substances, extensively used to give weight and opacity to the paper.

"The pulping operation is now to be performed. I would here state that for this purpose the present appliances are most rude and inefficient, there being no uniformity of result; some portions are thoroughly reduced, while others are hardly touched. Too much importance cannot be placed on this particular part of the process of preparing materials for the paper machine. I propose using an apparatus which rubs rather than cuts, so that with raw fibres, which are tender in the humid state, the greatest length is obtained. This object it is impossible to attain with the beating engine now in use."

In conclusion, the Doctor observed that there had been no marked improvement in the paper manufacture during the last fifty years, for the greatest difficulty had ever been, *not* to find materials, for such existed in great abundance, but to discover economical and practical methods of converting the same into good and strong paper. He had himself, some years back, endeavoured to introduce for this purpose the residue of the beetroot after the sugar had been extracted, which he considered one of the best and most available materials. It could be obtained, he said, in large quantities, at a low price, and had the advantage of not losing more than ten per cent. in the course of manufacture. His beetroot patents were in the hands of Messrs. Grosvenor, Chater, and Co.

The Chairman having invited discussion upon the foregoing paper,

Dr. Riddell said that the great objection against straw paper was its brittleness, arising from the quantity of silica it contained. He presented a specimen of a fibre which contained no silica, and which, he believed, might be prepared at a cost one third less than that of rags. He would also show some paper made from the fibre of the *Hibiscus esculentus*, a plant of about eight or ten feet high, yielding good food for cattle, while its bark contained the fibre referred to. He also named the fibres of the *Agave americana*, the *Sorghum saccharatum*, as suitable paper materials.

Dr. Watts, Mr. W. Hawes, and several other speakers, addressed the meeting in turn, but their remarks were not of a kind to interest our readers, being chiefly of a political, or politico-economical character. After having passed a vote of thanks to Dr. Collyer for his paper, the meeting adjourned.

NOTICES OF PATENTS.

Improvements in the preparation of Peat and Charcoal for Fuel, in the Manufacture of Coke therefrom, and in the Machinery and Apparatus employed for effecting the same. C. Kingsford.

Peat — that *ignis fatuus* of chemical inventors — has been tortured by every conceivable mode in the hope of forcing it to yield up some of the treasures supposed to be concealed within it. There is scarcely a substance that can be formed on paper, by adding together atoms of carbon, oxygen, hydrogen, and nitrogen, that has not been supposed to be obtainable from peat. Sanguine politicians have pointed triumphantly to the peat bogs of our much maligned sister isle as a perfect El Dorado. They have looked forward to the time when the epithet "bog-trotter" shall be a title of honour, not of derision; to the time when whisky, potatoes, and pork shall all be yielded directly or indirectly by the combustion of peat. Peat has formed the pivot round which systems of finance have revolved, and on which swarms of adventurers have lived; it has inspired the muse of some, and has proved the amusement of others, the prospectus-makers have praised it, the distillers have burnt it, the paper-makers have masticated it, the candle-makers have looked wistfully at its paraffin, the hatters have sniffed suspiciously at its wood-spirit, the water-proofers have taken the boiling point of its hydrocarbon naphtha; theorists have talked poetically of its pittacal, and, *facilis decensus*, water-closets have been deodorised with its charcoal. And yet the problem of the economical working of the peat bogs is yet unsolved; and, although we have unlimited faith in the powers of chemistry, we confess to preferring one acre of good wheat growing land to (say) six acres of the most intense bog ever trotted over.

Nevertheless, here is a new patent proposing a plan for converting peat into good fuel, and, moreover, the proposed process appears tolerably feasible, and contains none of the dreadful absurdities too commonly found in peat patents. The following is an abbreviated sketch of the final specification:—The patentee digs the peat, and while wet "pugs" it with a certain quantity of powdered pitch, the fibres of the peat thus become broken and felted, yielding a compact fuel which when coked yields a hard charcoal which the patentee says, well resists a blast. He also works up peat charcoal dust with pitch or resin, and after heating to about 300° F. moulds the product; it is subsequently carbonised in retorts. By this means the inventor states that he attains a very hard and superior coke suitable for industrial or metallurgical purposes. The chief part of the patent is taken up with a description of the pugging-mill employed; it appears tolerably simple and practical, but we doubt whether there is sufficient

novelty in it to allow of its being claimed. The general features of this patent are a straightforward and clear description of the patentee's meaning, and an absence of the absurd claims and unnecessary verbiage which disfigure so many chemical patents.

Improvements in the Manufacture of Artificial Fuel.
JAMES SHAW.

"THE object of this invention is to render the dust or small coal available for fireplaces of the ordinary kind by an admixture which will have even a better effect than the best kind of lump coal, and is effected in the following manner: — To a given quantity of small coal or coal dust I add about one fourth its bulk of lime, and thoroughly incorporate together, after which I slightly moisten the whole sufficient to bind them, when the mixture may be formed into suitable blocks by any of the known means, the result being that a more intense heat is obtained with less cost, and at the same time will last considerably longer than ordinary coal. This fuel is also well adapted to the generating of steam and other such like useful purposes."

We rather imagine that to bind coal and quicklime together by slightly moistening the mixture would puzzle even the patentee. Where is the extra heat to come from? Heat is generally in the ratio of the substances burned, but burn quicklime as he will, the patentee will not get more heat from it than was afforded by the fuel used to heat it. As for lasting longer than ordinary coal, we grant unreservedly that lime will stand the fire to any extent, and in this sense a pound or two of quicklime would be a most durable substance to have in a house. But quicklime dust is unpleasant in the eyes or nostrils, and to poke one of our patentee's fires would therefore require some courage. And then the furniture! In short, the patentee, after entering his provisional specification, evidently tried his process, that, doubtless, being a sufficient reason for his never completing it. There are hundreds of persons who have brought forward processes almost identical with that before us, and there are numerous patents involving the same idea.

CORRESPONDENCE.

The Truth of Latent Heat as an Explanation of well known Phenomena.

To the Editor of the CHEMICAL NEWS.

SIR,—In my last communication I made use of this phrase, but I must observe only as expressive of the existence of a certain order of phenomena; for that heat is ever latent in the sense now understood by philosophers I cannot persuade myself, and will briefly, although I hope fairly, set forth wherein this doctrine appears to me wanting in philosophical accuracy.

The heat produced by the slacking of lime is said to be owing to the water becoming solid, in which state it gives off that heat necessary for its fluidity. This supposes that water in its fluid state contains a certain amount of heat, although, according to our usual standard, it would be pronounced cold; and the supposition is evidently a correct one, inasmuch as its heat may be felt by plunging the hand previously into a mass of snow or ice, or better still, some freezing mixture. But the heat evolved is said to have been in a latent state; and this is a doctrine the truth of which I altogether fail to apprehend. Here we have apparently cold water poured upon a certain earth, and the product of this union is a considerable amount of heat, and an impalpable powder. This is obviously, according to the general and very vague acceptation of the phase, a chemical union; although, if a definition of this is required, it can only be said that the distinction between chemical and mechanical union lies in our being enabled to understand the latter, while the former phenomenon is not at present appreciated by philosophers.

Now I submit, with every deference for the opinion of others, that all the physical evidence we have is this: we find the union alluded to productive of considerable heat, and a certain powdered substance. Any speculation as to the direct cause of the heat cannot be said to come under this evidence, for all speculation is widely distinct from ocular or experimental proof. Yet it is of course fitting that we should logically investigate this question. And I must commence by remarking that the notion of anything existing in a latent condition appears to me peculiarly unphilosophical. We have heard of latent light, and to my mind the latent state of heat is quite as surprising and unintelligible. That heat can exist without being in any way capable of experience is a proposition which I must see absolutely necessary of acceptation before I can receive it. And in the example brought forward, as in fact concerning all phenomena where latent heat is supposed to play a part, it does not appear to me that we are brought to this alternative. The doctrine reminds me of one connected with metaphysics, where it is supposed that ideas may exist in the mind without being known to its author. This notion is now almost, if not altogether, cast away as absurd; and I apprehend that the similar doctrine of latency, as connected with any physical elements, must soon be refused by the philosophical community.

The cause of the heat appears to me to be exceedingly evident. A chemical action is produced in the way described: it will be seen that I am not bound to explain this, in order satisfactorily to account for the heat. As to the principle, it may, without doubt, be said to be that of the meeting of the various forces of matter, and their consequent interaction; or, if matter is but force, of the two material substances or forces themselves. Now force is nothing but a general term for friction; and the friction of these forces upon such an ether as I supposed in my last communication, would, when transmitted by it to the human frame or any other test, at once affect as heat. I admit that, for the present, we are not not enabled to demonstrate the existence of an ether, so that this explanation is suppositional; but, to my mind, it has none of the what appear to philosophical objections, appertaining to the doctrine of latent heat. And I consider it applicable to every case where latent heat is supposed truly to explain scientific phenomena.

And now to consider some other cases exclusively accounted for upon this doctrine. It requires 142°·65 of heat to liquefy a pound of ice, at 32°; after which process the water has not received any apparent heat: therefore, as it is supposed that the heat received must have produced some constitutional interaction, and as, moreover it is not sensible, it is set down as having become latent. I confess that to my own mind such an explanation as this is by no means satisfactory; and I doubt not that it arises from the strange doctrine of heat, which at the present time occupies the philosophical mind. Now in the above experiment, all the direct physical evidence we have is this: it is found that a certain amount of a certain substance, at a temperature of 32°, requires 142°·65 of heat to render it liquid, after which no accession of heat can be discovered. I see, however, no difficulty in explaining this phenomenon. Taking heat to be nothing more than the vibration of some ether, it is quite conceivable that the process of melting should prevent this being experienced, or more properly, that this process is the result of the vibration of such ether. After the liquefaction, apparently after the vibrations have been absorbed in this process, the thermometer rises, seemingly because these vibrations are not then so connectedly absorbed into the substance, but, as the vibrations of heat in their usual condition affect this instrument. It seems to me that the reverse of this experiment presents no more difficulty. A thermometer immersed in a vessel of water at 32°, does not sink while this is becoming solid, although heat is then known to be evolved. But after the solidification it of course registers its apparently decreasing temperature. In proof of the assertion with respect to heat, the same instrument would

rise if suspended over the vessel. It must be allowed that we know little or nothing of the motion of the particles of bodies, understanding this word how we please. And I apprehend it quite possible that the vibrational motion surrounding us, which we call heat, may so act upon the particles of a body, as to render it solid, without affecting an enclosed thermometer, and much less the duller apprehension or sensibility of the human frame. Consequently, whether water is artificially or naturally solidified, I see no reason for supposing the discharge of anything in the form of concealed or latent heat. In this example decrease of temperature, however brought about, produces solidification, with the presence of a certain amount of heat. As to the solidification, there is, as to the broad principle, little or no difficulty, it being known that heat, by repelling the particles of bodies, keeps them fluid, or in the condition of repose. It is the sensible heat evolved which has given rise to the doctrine of latency. Now it appears to me by no means impossible that the action producing solidification, as friction upon some ether, affects as the heat supposed to be latent. It may not affect the enclosed thermometer for the reason already offered, or because the ether, which, if the hypothesis is true, is contained in the substance, for everything will afford some sensation of heat, if properly examined, cannot be rightly acted upon by the atomic action, produced by the external diminution of heat, or by the heat vibrations themselves becoming fainter.

I am well aware that many phenomena connected with steam, will be considered altogether fatal to the explanation here set forth; yet I cannot say that such appears to me. When I consider the amazing amount of friction which the condensation of steam must generate, I can see in this an explanation of the heat which condensing steam imparts to many times its bulk of water. But I shall not now enlarge upon this. As to the heat produced by percussion and friction, I apprehend that the ether, which all bodies appear to contain, is set into vibratory motion by the percussional or frictional forces employed. And perhaps the ether surrounding all bodies is by these methods brought into action: and this most probably explains the heat produced by condensation or compression, where the ethereal element is only somewhat differently produced, and directed to a certain object. It has already been inferred that when solids become fluid, heat is absorbed. A notable instance of this is found in the freezing of mercury by a mixture of snow and chloride of calcium, which causes a very sensible diminution of the heat of the apartment in which it is performed. When I speak of heat being absorbed, I only intend to convey the idea of a vibrational ether penetrating the particles of bodies. It appears to me that such an element is both within and surrounding everything apprehensible to man; and I think also that this element is everywhere in a condition somewhat vibratory, inasmuch as there is no body, or combination of substances, except perhaps one or two freezing mixtures, which cannot by comparison be demonstrated to contain a certain amount of heat. And there is no reason at all for supposing that these exceptions can be pronounced cold; but, on the contrary, it is only philosophical to conclude that man is unable to rid himself entirely of the sense or presence of heat. I have endeavoured to unfold in these observations a general explanation of well-known and very important phenomena, less cumbrous and more intelligible than the now generally accepted doctrine. But of course these points would be nothing, were the question of truth not concerned.

I have met with the extraordinary expression of "heat of space." It is proper to conclude that those who make use of this and similar expressions, forget that upon no doctrine of heat, whether material or spiritual, can mere space be said to possess it. For space, as Kant remarks, is only the subjective condition of the mind, under which alone the knowledge of external things is possible.—I am, &c.

J. A. Davies.

MISCELLANEOUS.

To ascertain whether a Room is Damp or not.—Place a weighed quantity of fresh lime in an open vessel in the room, and leave it there for 24 hours, carefully closing the windows and doors. At the end of the 24 hours reweigh the lime, and if the increase exceeds 1 per cent. of the original weight, it is not safe to live in the room.—*Cosmos.*

Influence of Animal Food on the Colour of the Skin.—M. d'Abbadie, the African traveller, writes to M. Quatrefages, that the flesh-eating blacks south of Nubia have a much lighter complexion than those nourished on an exclusively vegetable diet. It is also pointed out that the negroes in Kabylie who eat flesh have a very light complexion, while preserving the crisped hair and all the other characteristics of the negro race.—*Cosmos.*

Covering Zinc with Brass or Copper.—To give zinc a coat of copper or brass for the purpose of a subsequent silvering or gilding, the following solutions are used:—for copper alone, a solution of sulphate of copper, saturated at the common temperature, is mixed with a solution of cyanide of potassium, adding as much of the latter as is necessary to dissolve the precipitate thrown down at first. The hydrocyanic acid disengaged during this operation must be carried off by a draught or flue. When the mixture is clear one-tenth or one-fifth of its volume of *liquor ammoniæ* is added, and diluted with water to density of 8° Beaume. For brass, blue and white vitriol are used in equal proportion, and prepared as before. Two parts of sulphate of zinc and one of sulphate of copper give a bright brass coating. Previous to their dipping the articles of zinc are rubbed thoroughly with finely-powdered pumice-stone and rinced in water, after which manipulation they are placed in the bath and remain there for 24 hours. After that time they are again rinsed in water and simply wiped off. The copper or brass coating has a very bright look, as if polished, and adheres perfectly. The thickness of the coat may be increased afterwards by the aid of a battery.—*Le Technologiste.*

Acidity of Brown Bread.—Liebig says that the objectionable acid taste which (the German) brown bread ordinarily possesses may be prevented by using some lime water in making the dough. He recommends about 50 pints of lime water to 2 cwt. of flour.

ANSWERS TO CORRESPONDENTS.

*** In publishing letters from our correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

Our usual "Chemical Notices from Foreign Sources" are unavoidably deferred till next week.

G. F. R.—The drawing was made to a scale of one half. Dr. Andrews has also employed a larger apparatus of a somewhat similar construction, but about twelve times the internal capacity of the one represented.

A Subscriber (Stratford).—*Œnanthic ether* is prepared by heating 5 parts sulphovinate of potash with 1 part of œnanthic acid. The mixture fuses and an oil rises consisting of œnanthic ether and an excess of œnanthic acid. The latter may be removed by heating with carbonate of potash. *Œnanthic acid* is obtained from the residue left in the retort on rectifying fusel oil over potash-ley. This residuum is mixed with dilute sulphuric acid, when œnanthic acid separates and collects on the surface in form of a fatty layer.

J. H. O. will be communicated with.

A Constant Reader.—The candidate is recommended for election by some fellows and members of council, and after some preliminaries is balloted for. Apply to Dr. Odling or Professor Redwood, the secretaries.

Received.—*A. Domeier*—*Mr. J. A. Davies.*

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Detection of Chromium in Presence of Iron, by F. H. STORER.

It is customary, in the methods of analysis now most commonly employed in laboratories of instruction, to rely upon the solvent action which the caustic alkalies exert upon hydrated sesquioxide of chromium as a means of separating this base from the oxides closely allied to it. It is well known, however, and the experiments of Northcote and Church [1] have determined the fact quantitatively, that when a small amount of sesquioxide of chromium is accompanied by a large quantity of the oxides of manganese, cobalt, nickel, or of sesquioxide of iron, it ceases to be soluble in the alkalies. From the frequency of its occurrence, as well as from the fact that it has the power of concealing a larger amount of chromium than either of the other bases which have been mentioned, the sesquioxide of iron in particular gives rise to much inconvenience in practice. It is a constant source of annoyance to beginners, who almost invariably fail to detect the presence of chromium in solutions containing it given them for analysis, if these at the same time contain iron also. In this case it may be detected, it is true, by fusing the mixed precipitate of oxide of iron and of chromium with nitrate of potash and carbonate of soda, and examining the aqueous solution of the mass obtained for chromic acid; but the student seldom applies this test, unless specially directed to do so. The operation is troublesome, since it necessitates the employment of a special set of tools, and occupies considerable time. It is as a rule distasteful to the student, and is rarely resorted to even by experienced analysts, unless the colour of the solution, a preliminary blowpipe test, or some incidental observation, has already indicated the probable presence of chromium in the substance under examination.

It is obvious, that if the chromium in the mixed precipitate could be oxidised in the wet way by some simple and rapid method, it would not only be more readily detected in any case, but the chances of overlooking it altogether, an event now so liable to occur, would be materially lessened.

Frommherz [2] long ago noticed that chromic acid is formed when an aqueous solution of a salt of chromium is treated with a solution of permanganate of potash, a fact which has since been corroborated by Reynoso [3], and still more recently by Cloez and Guignet.[4] Reynoso has suggested, moreover, that this reaction may be employed for the detection of chromium, especially if the chromic acid formed be subsequently converted into Barreswil's perchromic acid.

Chancel [5] on the other hand, has observed that chromic acid is formed when sesquioxide of chromium is heated with solution of caustic potash in presence of peroxide of lead, as may be shown by acidifying the filtrate from this mixture with acetic acid, chromate of lead being precipitated. He has also proposed [6] that this reaction shall be used as a test for the detection of chromium.

After a number of experiments upon the subject, I have satisfied myself that peroxide of lead is as good an agent as any at our disposal, if it is not the best, for effecting the oxidation of sesquioxide of chromium by the wet way, while the formation of perchromic acid is unquestionably the most delicate and characteristic reaction for chromic acid which we possess. This note, therefore, must be considered as being merely supplementary to the statements of Chancel and Reynoso.

Besides the observations of these chemists are those of Balard [7] that oxide of chromium is immediately changed to chromic acid when treated with a solution of hypochlorous acid; and of Carney [8] who has found that chromic acid is produced when a galvanic current is caused to flow through a dilute solution of caustic alkali in which sesquioxide of chromium, even that which has been ignited, is suspended.

For my own part, I have observed that sesquioxide of chromium may be converted into chromic acid in the wet way by the agency of several substances besides those already mentioned, and that the presence of free alkali, so far from being necessary, as has been implied by previous observers, with the exception perhaps of Frommherz, is not by any means essential in most instances to the success of the operation, oxidation occurring very readily in several cases in strongly acid solutions.

A dilute solution of chrome alum, which by experiment was ascertained to contain no chromic acid, was acidulated with sulphuric acid, a little peroxide of lead was added, and the whole boiled; on filtering, the solution was found to be of a yellow colour, and readily afforded the reaction of chromic acid when tested with dilute solution of peroxide of hydrogen, viz. a magnificent blue colouration due to the formation of perchromic acid.

A solution of permanganate of potash, acidulated with dilute sulphuric acid, being substituted for the peroxide of lead in the preceding experiment, produced a similar result. Peroxide of manganese also replaces perfectly the peroxide of lead in this experiment.

It is not even necessary that these mixtures should be heated. Dilute solution of chrome alum, acidulated with sulphuric acid, and mixed with a small portion of peroxide of lead, having been allowed to stand in the cold, was found to contain traces of chromic acid at the end of half an hour; after standing eighteen hours, a considerable quantity of chromic acid had formed.

A similar solution, in which peroxide of manganese was used instead of the peroxide of lead, gave a fine reaction of chromic acid at the end of eighteen hours.

A quantity of solution of permanganate of potash acidulated with dilute sulphuric acid, having been added to a dilute solution of chrome alum, also acidulated with sulphuric acid, retained its purple colour after having stood in the cold during twenty-four hours; at the end of this time, bits of paper were introduced in order to destroy this colour, after effecting which, the solution was tested: it contained no inconsiderable amount of chromic acid.

The foregoing experiments were all repeated, with almost absolutely identical results, with solutions prepared by dissolving chemically pure hydrated sesquioxide of chromium in dilute sulphuric acid. The formation of chromic acid in the cold may have been a little less rapid in this case than in the experiments with chrome alum; the mixture containing peroxide of lead, however, afforded an abundance of it when tested, after having stood two hours, and still more at the end of twenty-four hours. That containing peroxide of manganese also gave a fine reaction of chromic acid after standing twenty-four hours. The trial with acidulated permanganate of potash was not tested until the purple colour of the solution had disappeared; this was found to have occurred after the expiration of forty-eight hours; the solution was then yellow, and afforded the reaction of chromic acid.

(*To be continued.*)

On the Chemical Polarisation of Neutral Oxygen during the slow Combustion of Ether, by M. C. F. Schönbein.[1]

It is a fact well known for a long time that during the slow combustion of ether ozone or an analogous body is disengaged, and as it was found that during the slow combustion of phosphorus the formation of ozone was accompanied by the production of peroxide of hydrogen[2], it might be supposed that the latter would be produced during the slow combustion of ether. Experiment has shown that this is the fact.

To effect the slow combustion of ether, about a gramme of this body, and several grammes of water, are introduced into a bottle capable of holding about a couple of pints. A stoutish platinum wire twisted in a spiral form, the end of which is made red hot, is then introduced, on which the vapour of ether burns slowly at the expense of the oxygen of the air in the bottle, and a small quantity of peroxide of hydrogen is formed, which remains in solution in the water after the bottle is well shaken. To prove that such is the case, a few drops of a dilute solution of chromic acid, and a little ether, are added, which become coloured blue on agitating the mixture. This phenomenon is much more apparent if the platinum spiral be introduced ten or twelve times, the bottle being well shaken, and the air blown out every time. The ether then assumes a magnificent azure blue colour. The same tint is produced when chromic acid is added to an aqueous liquid containing peroxide of hydrogen, but in the watery solutions the colour is very fugitive, whilst in the etherial liquid it remains for some hours. The production of this blue colour at once indicates the presence of HO_2 in the liquid holding in solution the products of the slow combustion of ether. Besides this, the liquid reduces a solution of permanganic acid, peroxide of lead, the ferrates, and also the hypochlorites, with the disengagement of oxygen. It does not colour the tincture of guaiacum alone, but when some blood corpuscules, or a drop of a solution of ferrous sulphate are added, an intense blue is produced. It rapidly colours blue a mixture of dilute solutions of the red ferrocyanide and a ferric salt, which is not effected by ether alone.

All these reactions confirm the presence of HO_2 in the liquid. As the oxygenated water is formed under these conditions by the union of positive oxygen Θ with the water, we may ask what in this case becomes of the negative oxygen (ozone Θ), formed at the same time as the Θ by the polarisation of neutral oxygen. Experiments undertaken to ascertain this show that at the moment of its formation the negative oxygen Θ combines with *elayle*, a product of the transformation of ether.

When olefiant gas is introduced into a large globe containing ozone prepared with phosphorus and carefully washed, a white cloud instantly appears, and a body is formed possessing the following properties:—It produces violent irritation of the eyes, and rapidly colours blue paper imbued with starch and iodide of potassium. When water is introduced into the globe it is found to redden litmus, and gives an intense blue to starch and iodide of potassium paper. But it soon loses the latter reaction, whilst at the same time its acid property is increased. It will now be found to contain a sensible quantity of formic acid, produced by the transformation of the ozonised elayle.

The product of the slow combustion of ether then possesses properties which show at once the presence of HO_2 and ozonised elayle. It instantly colours blue the iodide of potassium and starch paper, and reddens litmus, and the acid exhibits all the characteristics of formic acid.

From these facts we may be allowed to draw the following conclusion:—During the slow combustion of ether, and under the double influence of heated platinum and the vapour of ether, neutral oxygen becomes polarised; the positive oxygen Θ combines with the elements of water and forms HO_2, whilst the negative oxygen Θ (ozone) unites, partly, at least, with elayle, to form ozonised elayle.

TECHNICAL CHEMISTRY.

On the Proposed Deodorisation of the River Thames by Means of Perchloride of Iron, by William Odling, *M.B., F.R.S., Fellow of the Royal College of Physicians, Professor of Practical Chemistry at Guy's Hospital, and Officer of Health for Lambeth.*

We must, I think, all admit, that if it were possible by any reasonable expenditure, to mitigate considerably the stench proceeding from the river during hot weather, as experienced more particularly during the last two years, such an expenditure would be highly advantageous. Although there is not one tittle of evidence to show that sanitary evils have as yet resulted from the offensive state of the river, it would, I conceive, be advisable to prevent the stench on account of its being a stench, and on account of the panic which its presence would create in the minds of Parliament, the press, and the public.

During the months of June, July, and August of last year, 17,700*l.* worth of deodorising material was thrown into the Thames through the sewers; while the material used weekly, during several consecutive weeks, cost as much as 2500*l.* That the use of these materials was attended with some degree of general advantage is, I think, unquestionable, and they were certainly of local benefit. At the same time I do not estimate the effects

produced by them so highly as do some. Thus I find that during the month of June the river temperature rose from 63° to 68°, and, simultaneously, arose the river stench. The average weekly temperatures during the four weeks of July and the first week of August were respectively 69, 73, 74, 73, and 70½°. During these five weeks the deodorising operations were at their maximum; but I do not find that any decided improvement in the state of the river occurred until the second week in August, when the temperature of the river gradually fell from 69½ to 65½°, after which time the stench obviously and progressively diminished. The deodorisation was discontinued on September the 3rd, after which date the river temperature did not exceed 60°. Judging from the remarks of persons constantly on the river, I do not think that the effects produced by the deodorants were quite as decisive as has been represented. The deodorising agents chiefly employed were chloride of lime, of which 478 tons were used, and chalk lime, of which 4280 tons were used. The expenditure on the chloride of lime probably constituted about one-third of the total expenditure. It is important to recognise the fact that these two agents act on very different principles. Chloride of lime destroys putrescible matter; lime merely delays the putrefaction. I consider that the money expended on chloride of lime was well spent, or at any rate, that chloride of lime was the most likely agent that could be selected to effect an abatement of the stench. But I have great doubt whether any benefit whatever accrued from the use of lime, which is a mere retarder of putrefaction. If we could delay the putrefaction of sewage until that sewage had found its way out of the river, we might hope to effect some good with lime; but this is quite impossible during the period of the river stench. It is not two or three days, or even a week's sewage, that has any morbid effect upon the state of the river. For the cause of the stench, undoubtedly, is the large proportion of sewage matter which accumulates in that portion of the Thames oscillating twice a day between Blackwall and Battersea. There was no obvious stench experienced at Battersea at low water, or at Blackwall at high water; but each locality suffered according as it came into relation with the comparatively unchanged body of foul water which was moved to and fro by every tide. In all probability the hot weather would have been quite inoperative in causing the sewage of the Thames to become offensively putrescent, if we could then have had the same amount of dilution and scour which exists now. But during the hot weather the quantity of water daily poured into the Thames was only about five times as great as the quantity of sewage, and the proportion of sewage in the mass of river water gradually approximated to such a ratio. The body of foul river water carried up to Battersea with every flow, and carried down to Blackwall with every ebb of the tide, received its daily accession of sewage, which oscillated to and fro for an indefinite period, before it finally made its way to sea. Now the process of liming retards the process of putrefaction for two or three days only, a delay quite inoperative in effecting any alteration of the river stench. Moreover, the putrescence of limed sewage when once established is of a most disgusting character. Again, the addition of lime to the river tends to produce an increased deposit of most objectionable mud. If, during the summer drought, the liquid sewage escapes with extreme slowness, the sewage mud escapes with still greater slowness. Every ebb tide deposits its filth on the exposed banks of the river, and while the water does not acquire a temperature above 70°, that of the mud may arise to considerably above 100°; and when this sun-acted-upon-mud is washed up by the succeeding flow, we above London Bridge experience the maximum of river stench. I think it most important to avoid the use of deodorising agents which, like lime, tends to produce any considerable increase in the quantity of river mud. At Leicester and Tottenham, where the process of liming sewage was adopted with great advantage, the clarified sewage carefully separated from the deposit of mud and filth was alone allowed to mingle with the streams.

Perchloride of iron, the agent proposed to be used by the Metropolitan Board during the forthcoming summer, corresponds in its mode of action rather with lime than with chloride of lime. Its chief action consists in retarding putrefaction, though at the same time it does act to some extent as a destroyer or oxidiser of putrescible matter. Drs. Hofmann and Frankland originally recommended this agent for one specific purpose. They proposed that it should be used as a substitute for lime, in the same manner that lime had been heretofore used at the Leicester and Tottenham works. That is to say, the sewage was to be treated with perchloride of iron, and allowed to stand at rest. The clear defecated liquid was then to be run into the river, and the deposit of filth to be carried away. From their experiments there can, I think, be no doubt as to the extreme applicability of perchloride of iron for that special purpose, and to its superiority over lime in the completeness, rapidity, permanence, and economy of its action. But the above described mode of dealing with sewage, and that proposed to be carried out by the Metropolitan Board during the present year, are entirely different, and it by no means follows that an agent which is the most suitable for the one purpose should necessarily be the most suitable for the other.

In comparing perchloride of iron with lime as a material to be cast into the sewers, and thence into the river, I should say that the advantages were nearly all on the side of perchloride of iron. Measured by its immediate effect, it is certainly cheaper than lime; Drs. Hofmann and Frankland estimate it at only half the price. It delays putrefaction for a much longer period than lime. It does not necessitate the production of so large a quantity of mud, and the mud which is produced will probably be of a less putrescible character. On the other hand, the mud produced by perchloride of iron is characterised by a somewhat rapid subsidence; in other words, it is more likely to be deposited than is the mud produced by lime. Another inconvenience which will probabably follow the use of perchloride of iron will be the darkening in colour, or even the blackening of the river. If the great object of the chemical treatment of sewage is to prevent popular outcry, I think any injury to the appearance of the river will be most prejudicial to such object. The black colour of the river most certainly would not give any real occasion for public alarm, but neither does the foul smell. Yet it is quite certain an offensive colour and an offensive smell are alike exceedingly liable to create alarm.

In comparing perchloride of iron with chloride of lime, I an not at all sure that the advantages are on the side of the iron salt. Chloride of lime is an agent of well established efficacy, which has been used as a deodorant under almost every variety of circumstance.

Perchloride of iron must be regarded at present almost as an experimental deodorant, and the circumstances under which it proved successful are very different from the circumstances under which it is now proposed to be used. I am informed that perchloride of iron, used in the manner in which it is proposed to be used by the

Board of Works, was tried at Croydon, where it proved completely unsuccessful.

Messrs. Hofmann and Frankland say that one gallon of perchloride of iron defecated 15,000 gallons of sewage, and that the clarified sewage remained sweet for nine days. Whether or not it then putrefied is not stated. The particulars of their experiments are not given, but one can hardly doubt that the clarified sewage remained sweet for so long a time, on account of its containing a certain amount of iron in solution. Now, this would not be the case in using the perchloride of iron in the manner now proposed. The clarified sewage, mixing with the calcareous river water, would very soon be deprived of its dissolved iron.

With regard to the putrefaction of the deposit produced by the addition of perchloride of iron to sewage, Messrs. Hofmann and Frankland's account is not very precise. They say: — "Having thus stated the results of our experiments regarding the process of deodorisation, it remains only to draw particular attention to the importance of discharging the sewage into the river as free from mechanically suspended matter as possible. We have found that this suspended matter, when separated even from the deodorised sewage, rapidly passes, in warm weather, into a state of active putrefaction. The removal of this matter would, in a great measure, prevent the formation of any offensive deposit upon the banks of the Thames, not to speak of the improvement in the appearance of the river which would thus be secured. We are therefore of opinion that filtration should be invariably employed at the outfall of the western division, and that subsidence, if not actual filtration, should be resorted to at the two remaining outfalls." From which I can only infer that the action of the perchloride of iron was found to correspond with that of lime. It produced a clarified sewage which might innocuously be cast into the river, but that, like lime, it also produced a sludge or mud scarcely less liable to putrefaction than the undefecated sewage itself.

Messrs. Hofmann and Frankland base their calculations upon the proportion that a gallon of perchloride of iron, costing 6*d.* and six pounds of chloride of lime costing 7½*d.* will equally serve for the defecation of 15,000 gallons of sewage. As the quantity of sewage poured daily into the Thames is about 5300 times this quantity, the Board propose to use about 5000 gallons of the perchloride. Each gallon of perchloride will consequently be mixed with 15,000 gallons of sewage, or 100,000 gallons of river water. Now, the tenders for the supply of perchloride of iron have not yet been examined, but I have very great doubts whether perchloride of iron of the quality required by the Board, that is to say, containing one pound of iron and only one ounce of free muriatic acid, can be supplied for anything like the price named. On the other hand, I know that chloride of lime can be procured for 7½*d.* per six pounds, and I think it probable it might be procured for somewhat less. I think the Board would have done well to have advertised for tenders for the supply of chloride of lime as well as for chloride of iron. They would have been in a position to say which would be cheapest.

[The Doctor concludes by expressing an opinion that in the present summer there will not be that remarkable drought which aggravated the stench during the two preceding summers, and recommending the use of chloride of lime, if the necessity for a deodoriser should occur. Dr. Letheby has also expressed himself against the use of the perchloride of iron.]

PROCEEDINGS OF SOCIETIES.

SOUTH KENSINGTON MUSEUM.

On the Animal Products in the Museum, by Ed. Lankester, *M.D. F.R.S.*

Lecture II. (April 17, 1860.) *On Wool and Hair.*

I propose to-night to leave the invertebrate animals altogether, and, reserving shellfish and other creatures belonging to that group for another time, to proceed to bring before you some of the products of the higher classes — the vertebrate animals.

Now there are various ways in which we might treat this subject. We might take up these animals according to their natural history classification; but the objection to this plan is, that we should have to repeat a great deal in one class of what was said in another, so that I propose first, to take the whole group, then the appendages to their skins, then the skins, and then the organs. All animals as well as plants are covered with what is called epidermis. If we take a brush and brush our arms we shall observe a quantity of dust to fly off. If we collect that dust and put it under the microscope we shall find it to be composed of a series of cells. Now these are called epidermal cells, and the whole of the membrane which lies at the top of the skin is composed of these cells, as well as the mass of matter which lies above the true skin and which we call the epidermis. It is this part which rises when we apply a blister upon the skin, the water coming from the true skin beneath and pushing it up. Now we find that this epidermis extends throughout the whole animal kingdom, and it is not confined to animals but is found also in plants. Thus if we look on the outside of plants we shall constantly find that there is a delicate membrane on the surface composed of cells which are much more dense and firm, and lie closer together, than those which are found immediately under. This external membrane then is called the epidermis both in plants and in animals. Both plants and animals constantly have an inclination to form appendages upon the epidermis—sometimes we call them warts and sometimes we call them hairs. Short hairs we call *pilli*, and when they have little glands at the bottom containing a secretion which stings us when we touch them — we call them glandular, such as the glandular hairs of the sting of the common nettle. Now these are the epidermal organs of the plants. We find also that when the membrane is carried into the interior of the plant that it forms a softer set of organs than it does when it is on the exterior. Thus we find that it lines the interior of the apple and the orange and other plants, and (more important to us) it lines the interior of the fruit of our cotton plant and furnishes us with cotton hair. These cotton hairs under the microscope have a little twist, giving to them a permanent bend which enables us to twist them into a thread which can be woven into a fabric, and whatever importance we possess as a manufacturing nation we owe to cotton first, then to wool, then to silk, and next to leather. In our manufacturing industry we use the hairs of animals and they may be woven in the same way as the hairs of plants.

And now I wish to draw your attention to the fact that the epidermis of animals will produce hairs just in the same way as it produces hairs in plants, and not only hairs but a variety of organs which we do not recognise by the name of hairs. We should hardly call a corn on our toe a hair, and yet it is an epidermal appendage of the same character. We should hardly call the horn of the rhinoceros a hair, and yet it is formed in the same way. And in the invertebrate animals, crabs, lobsters, insects, shellfish, if you examine them you will find that this external membrane has become converted into a skeleton, and thus we call them epidermal skeletons. And if we pass from those lower to the vertebrate animals we find them producing a variety of appendages upon their skins, the object in view being the preservation of the life of the animal. Take the fish, for instance, the

most distinguishing features of the fish are its scales, and the variety and adaptation of its scales, which are joined the same as the epidermal hair of plants, and are formed of a similar series of cells. We classify fish in our natural history classification according to the form of their scales, and it is by these the philosopher is able to determine their species. Again, the feathers in birds are modifications of the same organs, and we sometimes find in the *mammalia* organs very much like feathers, as in the porcupine and hedgehog. Then we have in the mammalia animals with hoofs and horns which are also epidermal appendages. When we examine the horns we find they are an immense collocation of the hairy substances. Ruminants and pachydermatous creatures have hairs. The claws and bills of birds, our own nails, for instance, are formed like this hair. Now I want to call your attention to the way in which this hair is formed. You will recollect that there are little depressions in the skin like holes called hair follicles. Those follicles are filled naturally with an oily matter, and when the hair is formed we have little bloodvessels which supply the lower part of those follicles, and cause the cells to grow faster at the bottom, and thus an organ of this kind is pushed out. Corns are formed just in the same way. When you have a tight boot you make a pressure which causes increased nourishment of the epidermis, which results in the painful growths of which so many complain. So with warts, they are an excessive secretion of these epidermic cells.

Now the subject I want to bring before you is wool, not hair; but this wool is nothing more than a modification of hair, and we call it wool because it has a tendency to curl. We say when a man's hair curls and is crisp that he is woolly headed, and there are woolly headed races of mankind. Well, that tendency which we occasionally find in the human race is constant in certain animals, which accordingly yield this substance we call wool; and we shall find that the growth of this wool is attended with certain alterations by which it becomes useful for certain purposes for which we cannot use hair. We cannot weave human hair. We cannot felt human hair. We cannot make the warm garments with hair that we can with wool. If you put a piece of human hair under the microscope you see that the exterior is composed of scales which overlap each other so as to present an imbricated appearance. Now if you put wool under the microscope you will see that the exterior presents a serrated appearance, which is much more developed in some wools than in others. It is only after long boiling and treatment with sulphuric acid that you can get human hair to look in the same way with the scales all spread. Now it is dependant upon these woolly hairs possessing looser scales that they are of use in the arts. That the use of wool depends upon those imbrications is seen in the kinds of wool more extensively employed in the manufacture of cloth. There are several calculations of these serratures. Mr. Goss finds that the finest Saxony wool contains 2720 in a single inch. Now that Saxony wool is used for making superfine cloth, and it is a kind of wool that we never get from English sheep. Some merino wool presented to Mr. Goss showed 2400 serrations to the inch. Now we come to our own Southdown fleeces, which are known by manufacturers to be inferior to the Saxony wool, and Mr. Goss found in Southdown wool 2080 serrations to the inch. Next we come to our Leicester wool, which is still less valuable, and in this we find only 1850 of these serrations. Now that calculation has but recently been made, but it proves that those serrations have some relation to their use in the manufactures; and now that that is made out the manufacturer will know how to detect the quality of the wool by the use of the microscope. It is all very well for men to say "we can use our hands and our eyes as we have done from the time of Adam, and we do not want any of your new-fangled instruments;" but that is like a man rejecting the use of one of his eyes because his grandfather had only one eye. By the use of the microscope we can detect qualities in the wool hitherto unknown even to the practical man. These serratures then are of great importance in the history, and indeed in the manufacture of wool, and it would appear that that process which is called felting, depends entirely on those little serratures becoming entangled one in another, and thus a piece of cloth is made without weaving. You cannot too early know the distinction between the uses of the different kinds of wool. One kind is converted into what we call cloth by the felting process, and another is converted into what we call worsted, or stuff, or stockings. These are made from the hair which does not felt well, and we find that it is just in proportion to the number of these serratures that the cloth will felt well. The longer the wool the less the number of these serratures in the inch, and the shorter the wool the greater the number. All the short wools are preferred for the cloth manufacture, and all the long wools for the worsted manufacture. We have instances of the use of wool for felting, which show that the process of felting has been known almost from time immemorial. As to other hairs, those of the stoat, the mouse, the sable, the rabbit, the dog, the cat, and the hare almost all felt as well as the hairs or wool of others of the *rodentia*. And here I may remind you of the beaver hat which is becoming almost as scarce in this country as the beaver himself, for these hats are now but seldom used. However, here are some portions of the illustrations of the process of felting a hat. Here I have some beaver hair, and here is some lambs' wool which they mix with the beaver hair. Now lambs' wool will not felt, but it has the curious property of facilitating the felting of the beaver hair; hence you find that the beaver hairs are knocked together with the lambs' wool, which comes out to the surface like cream upon milk. You may see the whole process illustrated in Mr. Roberts's case in the museum. There is also a beautiful specimen of cloth in the museum, sent down to this Institution by Mr. Roberts, which consists of the hairs of the rabbit felted, so producing a beautiful piece of cloth,—a cloth which I should think is likely to be used for a variety of purposes in the arts. That is just then an instance of the fact that other hairs besides wool will felt. Now I have sometimes suspected that this property of felting is not solely due to these serrations, these imbrications so clearly developed in the wool of some animals, for I have remarked that in all the cases of the best felting hairs you always see a kind of hole or cavity in the interior, which allows the hair to yield to pressure upon a part, and thus the hair becomes reduced to a third or half of its bulk by the process of felting. I throw this out as a hint to those interested in the process. Now I come to the chemical nature of hair. I told you in the last lecture that the animal kingdom was distinguishable from the vegetable by its fabrics being generally composed of gelatine instead of cellulose; but that was a generalisation not without great exception: for in fact these hairs and that silk which I spoke of on the last occasion of our meeting are not like gelatine. When we put them into boiling water they do not dissolve, and we could not wash them if they did. The composition, however, is after all very nearly that of gelatine, and there is some difficulty in ascertaining what is truly the nature of this epidermal substance, when it assumes the form of the hair, the nail, the hoof, the quill, and of the scale. Those substances have been examined by the chemist, who has not found anything definite in them. If any of you are chemically inclined, I will put them down in symbols C.H.N.O.S.

I do not think you will make much out of that. The fact is, I have not been able to make anything of it myself, at the same time it is quite possible for some of you to understand it. We have, you see, the four organic elements, carbon, hydrogen, azote, and oxygen, and it seems probable that when these matters have been used as muscle and nerve, that a certain quantity is passed off to the skin and there it forms the epidermal organs. But during that process it combines with a quantity of sulphur (for all these substances contain sulphur), and that is how they are distinguished from the gelatine, which does not contain sulphur. That is not exactly all I can say with regard to the chemical

composition, but I have no doubt the time will come when the chemist will understand of what these epidermal appendages are formed, though the subject has not yet been successfully taken up by any chemist that I am aware of. Now I wish to speak of the sources of wool. Everybody knows we take it from a sheep. What is a sheep? Can anybody tell me the difference between a sheep and a goat? Yes, you say. Then if you can tell me in a very few words you will confer a benefit on the naturalist. You find that the wild sheep run into the wild goats. The llama, the vicugna, the guanoco, the camel, and the dromedary are so closely allied that we are puzzled to know where camel begins and where alpaca ends. So it is with the sheep — there are wild sheep. There are the *argali*, which live in certain portions of Asia, distinguishable from our sheep; and there is also the *argali* of America, the sheep which is called *ovis montani*. Then there is a sheep which inhabits the Islands of Greece. It is very certain that the old sheep which we read of in the Bible was not a descendant of that American sheep in any way. Then the question is whether it descended from the *argali* of Asia or the *musimon* of Crete or of Greece. There is considerable difficulty in getting at those lines of distinction, and we speak then of our sheep as an independent species. Now the great and individual features of our sheep have been maintained through a long period of time. The sheep we have at the present time seem to be identical with the sheep of old. The sheep of Judea seem not to have differed from the sheep of the present day, and when we read in the Bible of the tending of sheep and their management, we feel that the sheep of that day were like the sheep of the present day, that their habits were the same, their domestication was the same, and their uses were the same; for we find the man of that time eating the mutton, and using the skins for clothing until he learned to weave the wool, and then he made cloth garments. Now we have what are called breeds of sheep, and those breeds of sheep are somewhat difficult for persons not acquainted with agriculture to determine. There are, however, in the Museum a number of heads of sheep constituting a large variety which have been employed in the production of the wool in this country. We may divide them into the old mountain sheep, the early inhabitants of our island, and those more recently introduced, which are sheep of the plains. You all know the little Welsh sheep having a leg not weighing more than two or three pounds, hardly enough for a strong man's dinner. They have so small a crop of wool that it is hardly worth while shearing them, therefore they are going out of fashion. There are people from Wales who like Welsh sheep as the Scotch like Scotch sheep, and thus the kind is kept up. But there would have been no Leeds and no Bradford if there had been none other than Welsh sheep. Little sheep generally bear small fleeces. The Welsh and Irish generally yield no more than 2 lbs. and the Leicester as much as 8 lbs., and in America we have recently been informed they have a fleece of 18 lbs. The tendency in this country in the breed has been to get a large amount of wool, but at the same time you ought to know that in this country we do not produce the finest kind of wool. The long wool sheep yield a valuable produce, but it is the short wool sheep which produces the most valuable. That, however, fails to equal the short wool sheep of Germany, of America, and more especially of Australia, and all these are surpassed by the Spanish sheep. The merino sheep, originally reared in Spain, produces the finest finest quality of wool for the manufacturer. This wool is short, and covered with a sticky secretion, and we can easily see in this wool that it makes the finest quality of cloth that is worn. Hence it was that, many years ago, the attempt was made to introduce the breeds of merino into England. They succeeded to a certain extent, but our climate was too damp and not sufficiently warm to develop their produce, and I believe there is not now a single merino sheep in this country, although thousands of pounds have been spent in the attempt to breed them. Our manufacturers obtain their merino wool from Spain, but at one time the law forbade the importation and exportation of wool, and we were then confined to the produce of our own soil. It was at that time that the sheep were introduced from Spain. Spain has lost much of her prestige and much of her industry, and when one hears of the climate of Spain and the vast resources of that country, one grieves to think it is doing so little among the nations of Europe. But what has not been done by Spaniards has been done by Englishmen. A few of these merino sheep found their way to Botany Bay. I do not mean to say that any cunning sheep stealer carried away a flock of these sheep while he was paying the penalty of his malversations. At any rate they were carried there and afterwards neglected, but in spite of that they flourished and increased; and from that small beginning has arisen an enormous trade; and now our largest supply of best wools is from our colonies in Australia. We get other kinds of wool from Saxony, and Saxony wool is perhaps the best spinning wool known in the world. All German wool, however, is not so good, but we get from Germany large quantities of the finest kind for cloth. At the present time we are deriving a considerable quantity of fine wool from America, and America is carrying on its woollen manufacture from the production of its own sheep. Many parts of North America produce very fine wool. It would seem almost hopeless for the English farmer while he produces very fine mutton to compete with America, Germany, and Australia in the production of the best wool; but at the same time the mixture of breeds has presented us with very fine wool, and the day may come when we shall produce the best mutton for our tables and also produce the best wool. I have not time to speak of Chinese and Indian wool and the wool of other portions of the world. We obtain it from almost every part, but none is more remarkable than those which I have mentioned. Now I will just refer to other animals which yield us wool as well as sheep. You will find in some of the cases in this museum that the camel yields a wool which is occasionally woven by the women of the country into a kind of coarse garment. The other creatures which come in competition with the sheep are the goat, the llama, the alpaca, the vicugna, and the guanaco. The goat itself is difficult to distinguish from the sheep, but the common goat does not produce anything like the quantity of wool that the sheep does. But in certain parts of the world the goat produces very fine wool which has been manufactured into the finest garments. It yields a fleece of from 1½ to 4 lbs. of fine fleecy long hair. In 1848 it was first brought into the markets of Europe. I will just remark in passing that what we call velveteens and plushes are mixtures of cotton and wool. Silk and wool are also mixed, and these hairs of the Angora goat are particularly well adapted for this mixture. There is a goat in Cashmere which yields an exceedingly fine wool, which is employed in the manufacture of those beautiful Cashmere shawls which are such objects of desire to those who wish to appear in the most beautiful forms of dress. This goat yields a fleece of which about 30 ounces are sufficient to manufacture a shawl a yard and a half square, and the worth of the 30 ounces is 8*s.* or 9*s.* Then why do these shawls cost 600*l.* and sometimes 700*l.*? In answer to that question I will read a passage from the catalogue of this Museum. "Thirty ounces, valued at 8*s.* or 9*s.*, are all that is required in the manufacture of a shawl a yard and a half square. The immense cost of these shawls in the European market is therefore a subject of much wonder to those unacquainted with the history of their manufacture and transportation. A heavy duty is first paid upon the wool, then a further tax upon the yarn when it reaches the bazaar, and the manufactured shawl when taken to the custom house is further taxed according to the direction or caprice of the collector. If intended for the European market the shawls have yet to pass through the ordeal of still heavier exactions. They must be borne from Cashmere across the Indus to Peshawur on the frontier of Affghanistan, a journey of twenty days, upon the back of a man

the road being often impassable for camels or mules, deep precipices being crossed by suspension bridges of rope, and perpendicular rocks climbed by means of wooden ladders. At various stages of this journey taxes are exacted amounting to 36*s.* or 42*s.* in the aggregate. From Peshawur to near the confines of Europe tribute is paid at many custom houses, and the forbearance of the marauders of Affghanistan and Persia and of the Turkomanic hordes must also be purchased at a high price. The precious burden is thus conveyed to Europe over the Caucasus and through Russia, or, as is now frequent, through the Turkish provinces to Constantinople." You see our friends in Cashmere are not aware of how fully we have discussed the question of free trade, and determined that it is best for the extension of trade. You need not wonder then that those beautiful shawls manufactured from the hair of the Cashmere goat should sometimes reach a price of 600*l.* or 700*l.* before it passes the rocky portals of the valley of Cashmere.

But I now pass to a kind of animal that has only recently yielded produce for our backs, but which is likely to increase the quantity of our cloth. I allude to the alpaca, which is allied to the camel and dromedary. When Cortes conquered Mexico, and Pizarro Peru, they found the llama employed as a beast of burden. The Mexican and Peruvian government have placed an embargo upon the exportation of these creatures, so that we have only now and then seen them as curiosities in the collections of our zoological gardens. But in 1846 it appears some of the wool was carried to Bradford. I recollect a gentleman of the name of Dennison coming to the meeting of the Association for the Advancement of Science, who endeavoured to convince the association of the importance of the wool. Upon one occasion he brought six of the animals to the association, but notwithstanding all that was done the alpaca wool was neglected, and much of it was lying and spoiling in a cellar, until an enterprising gentleman, named Titus Salt, bought the whole, and succeeded in laying the foundation of one of the largest enterprises in this country, and thus conferred a blessing upon his own country as well as the countries from which the animal can be obtained. The length of this hair renders it of considerable importance for mixing with the mohair and goat's wool. I would mention that there are four of these animals very distinct in form, as may be seen in the llama, the alpaca, the vicugna, and the guanaco. The vicugna yields very fine hair, which is not very much valued, but the alpaca yields a kind which is highly prized. I have mentioned the advantage of acclimatising other animals. There is no difficulty apparently in Australia, though where they have attempted here rot has seized them, because of the tenderness of the feet. A few months ago several alpacas were secured, somehow or another, and sent over to Australia; whether they have arrived there and are flourishing, I know not, but that is an experiment which ought to be encouraged, for we know not how much it may extend our manufactures.

I will now call your attention to the manufacture of wool. This wool has to be taken from the back of the animal. Like all these other epidermal appendages, it is liable to be cast off. There is one peculiarity of this epidermis, that if creatures do not throw it off by what we call a moult, it is continually going off. We are continually moulting, but occasionally large quantities of hair come off, and this is moulting. At the same time the process is a natural process of moulting. You see it in the antlers of some creatures and the horns of others, in the hair of all the mammalia, and the feathers of birds, and the scales of fish. This wool would fall off, but men come in and prevent the falling, and the trouble of picking it up, by shearing. But there is a process first of washing. If you look at the fleeces in our museum it is always stated that it was washed on such a date, and that washing is necessary to make it available for the manufacture. At the base of those hairs a kind of soap is formed of oil and potash, which is a kind of natural soap for mixing with the impurities of the hair, and the grazier takes advantage of this soap. Sometimes various lyes are used with the addition of various substances for killing insects, but generally these processes are bad, and the only thing necessary is to take the animal and wash it in soap and water, and afterwards in clear water. The shearing takes place in the spring of the year and in the autumn. Everybody has seen the lambs after shearing, when their mammas have stared at them in their new appearance, and when it was only by their bleating that their mammas have recognised them.

Now the next process is an interesting one—assorting and stapling. The wool got from an animal is not all long or short; even the short wool sheep have some long, and the long wool sheep have some short wool.

Well, this process is a very interesting one. The persons who do it are called woolstaplers. They take the fleeces in their hands and they sort it out. There are fancy sorts, colours, cleansed, and waste, all to be stapled, and it depends upon the object of the seller how it shall be stapled.

Now, then, we take our stapled wool to the manufacturer, and now this wool is scoured or washed. It contains a good deal of dirty matters of various kinds; it contains grease, lye, animal matter, and it is exposed to various substances which take out the ammonia and oily matter, and frequently, after being scoured, it is submitted to pressure in order to dry it.

Then comes the dyeing process. It frequently occurs that the manufacturer wishes to dye in the cloth, and with his lighter and brighter colours that is always the case. After the wool has been dyed, it is submitted to a process called willying, which merely means arranging the wool so that the fibres are laid parallel to some extent; and after this is done a further process of picking is employed, and then comes this process of scribbling which is antecedent to the carding. This carding seems to be almost as important as the felting, for it is this carding which breaks up the wool, and gives it a tendency to curl. If you look at a piece of felted cloth the pieces of wool are curled, and you cannot get the curl out of them; and you find that the carding which breaks it up is almost as important as the felting. Then the spinning takes place, and the reeling and warping, and then we have another process of scouring, for they have added oil, and during the process of spinning they cause the thread to pass through size, so that the threads may lie close together. And now you have to add potash to get rid of the oil, and soap and water to get rid of the size. Then after the weaving you have the fulling—the fulling is effected by enormous wooden hammers which are allowed to drop on to the cloth. By this hammering the cloth is reduced to a condition in which its strength is fully developed. Whilst it has been unfulled it has been weak and easily torn, but now it is not easily torn. After it has been fulled it is again scoured, and then it is submitted to a process which is called teazling, or cleaning, or brushing, or raising. This process consists of applying the little bodies which are called teazles. The object of this teazling is to bring up the loose particles of the wool, in order that they may be sheared or cut off, to give the cloth the fine appearance it assumes. Now look at the teazle. Man has invented nothing which can take its place. This teazle is remarkable for producing its epidermis with spiny bracts, the end of which curls downwards; and if you get a teazle in the road at any time and brush it on your hand you will feel the effect; and then if you pass it along your cloth you will find that it will rub it up, and raise the surface. Now various instruments have been employed: a series of pieces of wire have been run into a leather back, but nothing has superseded the teazle. We import these teazles in large quantities from France and various portions of Europe. After the shearing and cropping has been gone through, then comes the pressing and rolling up, and doubling up, and pressing and packing.

If time had permitted, I might have said something of our enormous woollen trade. There is no other, except the cotton, which is greater. For worsted you take a hair, not for the purpose of felting it or of carding it, for you neither

card nor felt in the worsted manufacture, but we take a wool that is long. The very first process is not to imitate those serratures, but to fold them down softly and bring them down as closely as you can by means of oil and an iron comb, and this is called combing, which is almost the same process as with the cotton. You have then the same process of cleaning and making yarn which are run into fine threads, and these threads are woven together in the ordinary manner like cotton; the roving takes place in just the same way, and the particles are twisted together. We distinguish between woollen and worsted manufactures. Woollen consists of broad cloths, carpets, blankets and serges, so that you see how important is the manufacture. The worsted is no less important. Stuffs, bombazines, camlets and shawls, are all instances of the worsted manufactures. The woollen produces a warm and heavy garment, while the worsted produces a light and loose as well as a warm garment.

Thus you see the value of the culture of the animals around us. In course of time we may find, if we learn our lesson rightly, that there is nothing created for us in vain, and that whatever God has made He has created for the use and benefit of man.

SOCIETY OF ARTS, *Wednesday*, 25 *April* 1860.

EDWIN LANKESTER, *Esq., M. D. in the Chair.*

† DR. JOHN DAUGLISH read a paper to this meeting of the Society describing in detail his *New System of Bread Manufacture*. After a few introductory remarks, he said:—

"Bread-making essentially consists in completely incorporating flour, water, salt, and carbonic acid with each other, in such a manner as that they shall form a tenacious, elastic, and bulky mass, in which the aeriform constituent bears to the solid a proportion of about three or four to one, and which, on being placed in the oven and thoroughly baked, shall swell to about double the proportion.

"Until very lately the mixing and incorporating of the solid constituents have been performed by the hands and arms, sometimes assisted by the feet; but during the last few years, especially in France, there have been some very ingenious kneading and mixing machines introduced for this purpose, that of M. Boland being of especial merit. The mechanical part of bread making is very easy of accomplishment, and in results, like all mechanical processes, can always be relied upon with certainty. It is the chemical part out of which all the difficulties and uncertainties arise, and which has presented the only obstacle in the way of bread manufacture participating in that marvellous progress of the industrial arts which is the distinguishing feature of the present age—and of its taking that position as a manufacturing institution of the country which its magnitnde and importance deserve.

"The chemical changes within the substance of the dough which it is the object of the baker to effect, are those which shall result in the alcoholic fermentation of transformed starch or glucose, whereby these bodies are broken up into alcohol and carbonic acid, which latter is the only product desired, but which cannot be obtained without the previous transformation or degradation, more or less, of the constituents of the flour. It is not necessary for me here to give an account of all those complex changes which constitute the chemistry of bread making, as this has already been so ably done by Dr. Odling, but I will simply mention those which are the source of so much uncertainty and variation in the preparation of bread.

"In the first operation of bread-making—the preparation of the sponge—the baker mixes up together, into a soup-like paste, flour, warm water, and yeast or leaven; this he allows to stand for some hours, during which active fermentation is set up, and bubbles of carbonic acid are rapidly formed, and rise to the surface. In fact the prolonged action of warmth and moisture combined with that of the yeast or leaven, change the whole body of paste into a ferment sufficient to effect a very large quantity of flour when incorporated with it. You will hence perceive that by thus forming a sponge. the necessity to use large quantities of yeast is avoided on the one hand, and on the other the length of time that would otherwise be required for putting the whole of the flour into a state of active fermentation is considerably shortened, and the deterioration of the flour, which is caused by the prolonged action of warmth and moisture, proportionally lessened.

"The advantages thus obtained will be more readily seen when it is remembered that the true alcoholic fermentation is only the later stage of what is termed the panary fermentation. It is that stage wherein the metamorphic nitrogenous body or yeast acts directly upon glucose or grape sugar, breaking it up into alcohol and carbonic acid. But before this can take place, since in sound flour there is very little, not more than a trace, of sugar, and the gluten is nearly or wholly introduced, certain portions of the gluten and starch must have passed through the necessary changes for the alcoholic fermentation to act. This then is done in the sponge, when the mixture of flour, yeast, and warm water is made, and the temperature is maintained at about 48° Fahr. The gluten, by virtue of its own spontaneous tendency to change under these conditions, assisted by the yeast, becomes metamorphic, and immediately acts upon the starch, changing it into dextrine and grape sugar, whilst at the same time the yeast plant is propagated at the expense of a small portion of the changed gluten, &c. Thus we have in the sponge all the materials, the dextrine, and glucose, the diastase and the yeast, in a state ready to pass into active alcoholic fermentation, and to give off the necessary bubbles of carbonic acid immediately their complete incorporation with the flour is effected, so that the least possible injury to the bulk of the flour is secured.

"But when unsound flour is used in bread making, we have a very different state of things. Unsound flour is flour in which some of the changes on which panary fermentation depends have taken place to a greater or smaller extent, which are somewhat analogous to malting. The gluten has already become metamorphic, and the starch partially or wholly changed into dextrine or glucose. The gluten has lost more or less of its elasticity, and is ready immediately on the application of warmth and moisture, not only to pass rapidly into a state of solution, as Liebig has termed it, but to act with the greatest energy on the partially changed starch, completing its alteration into glucose, so that a running sticky mass results from the attempt at fermentation. Such a state of things, however, may be and is frequently brought about, even when good sound flour is used, either by inexperienced persons, who do not understand the management of fermentation and the length of time and the temperature necessary, or by peculiar states of, and changes in, the atmosphere, by which the fermentive operations are so rapidly hastened in the earlier stages as to become almost or quite unmanageable.

"Between perfectly sound flour and that which runs in the manner above referred to, on the application of a ferment there are indefinite shades of variety; and between the temperature and the state of atmosphere least liable to produce derangement and that which is most, there are also indefinite varieties. Now it is these liabilities to derangements and irregularities that have rendered the preparation of bread so precarious, and which, going along with the absolute necessity to have the article ready always at the same hour of the day—an article which, in the event of its spoiling, cannot be reprepared under eight to twelve hours—have raised an effectual barrier to its becoming an extensive manufacture in large establishments, employing large capital, and deriving the peculiar profits arising out of the division of labour.

"Having thus pointed out the distinctive features of the ordinary process for obtaining the complete incorporation of the essential materials of spongy bread, I will proceed to describe the process which it is proposed to substitute for it.

"It essentially consists, as I have said, in doing away entirely with fermentation, and with all those chemical changes in the constituents of the flour which are consequent upon it; and having obtained the necessary carbonic acid independently of, and separate from, the flour, incorporating the materials, including the carbonic acid, wholly by mechanical means, so as to secure the bulky elastic mass which is capable of being baked into light spongy bread.

"When wheaten flour, salt, and water are thoroughly incorporated in due proportions, we have a heavy, soft, tenacious substance, called dough or paste, the tenacity of which is wholly dependent on the mechanical condition or properties of the gluten of the flour, the starch, when in a sound state, possessing of itself no cohesive properties whatever, which is easily demonstrated by kneading a mass of dough carefully in a small stream of water, when the starch granules will be carried away by the water, and the gluten will remain behind in a tough, tenacious, semi-transparent mass. The process of kneading or incorporation, then, consists in mixing the materials together in such a manner as that the gluten, becoming well saturated with water, shall form a soft adhesive mass, as a matrix, in which are embedded and bound together the minute particles of starch, and if the kneading is carried on in a very thorough manner, and for a prolonged period, the dough becomes tough by the particles of gluten being driven close together, and forming a kind of sticky coat or shell around the particles of starch which thus adhere firmly together. When this mass is obtained, the point afterwards to be effected is the liberation of minute bubbles of gas within each sticky coat, surrounding each granule of starch.

"We have seen that in the ordinary process of bread making by fermentation, the carbonic acid, which is the agent of distension, is obtained from the decomposition of the starch or glucose, by the action of a ferment, which being thoroughly incorporated along with the other materials, into the dough or paste, is thus brought into contact with the starch and with the gluten with which the starch is surrounded. It is easy, therefore, to understand how, when a mass of dough thus constituted is left for a time in a temperature suitable for the fermentive change, the minute particles of starch, each imprisoned in a covering of gluten, is made the centre of a distinct chemical action, and yields up its bubbles of carbonic acid to distend its gluten coat, and how, by the aggregation of such particles, a mass of spongy dough is formed, and how, also, when the materials have not been thoroughly incorporated, and the action of the ferment is not uniform, or when the gluten is not of a firm yet elastic quality, the generation of the gas will be unequal — the minute bubbles will be burst into large ones, and the texture of the dough be impaired accordingly, rendered as it is termed 'full of eyes'—instead of being dispersed in minute bubbles, as numerous, or nearly so, as the particles of starch from which it is given off. In the new process, as the gas is not given off by the particles of starch within the gluten coat, it has to be obtained from another source within the mass of dough, in order that the minute spongy texture may be secured, and this source is the water with which the gluten which envelopes the starch is saturated, and which is held, as it were, by capillary attraction also, around the particles of starch.

"It has been long known to chemists that water will absorb its own bulk of carbonic acid, whatever the density, with great readiness when agitated with it; that is to say, supposing you placed water in a closed vessel along with carbonic acid—in a bottle for instance—filling it half with water and the other half with the gas, then cork it up; if the water and the gas be pure, and both at a temperature of 62° Fahr. and at the atmospheric pressure of 30 inches of mercury, when the bottle is thoroughly agitated, the gas will be immediately diffused through, or absorbed by, the water, until there is an exact balance between the quantity of gas held in solution by each cubic foot of water and that contained in each cubic inch of space within the bottle not occupied by the water; so that, supposing the bottle at the commencement of the experiment to have been exactly filled, half with water and half with gas—after complete agitation the barometric pressure within the bottle will have fallen to 15 inches of mercury. This law of absorption is persistent at all pressures, so that by increasing the density of the gas, the quantity absorbed by the water will be increased in an equal ratio, and so long as the water is retained under the pressure due to the density, so long will it hold the gas in solution, but whenever it is released from the pressure the gas will escape with effervescence, a familiar example of which is that of a bottle of soda water when the cork is withdrawn.

"It will now be apparent that if water, holding in solution the necessary quantity of carbonic acid gas, could be used to incorporate with flour, &c. in the preparation of dough, without any of the gas being allowed to escape from it until after the paste is fully formed, but then allowed to escape, it would cause the formation of the necessary minute bubbles of gas, which would distend the dough into a perfect sponge, even more perfect than that which is obtained by fermentation, since every atom of water would yield its atoms of gas, not only between the particles of starch and their gluten coat, but also within the substance of the coat itself, rendering that porous.

"Now, since the water will retain the gas in solution so long as it remains in an atmosphere of the necessary density, it is evident that if the materials of which the dough is to be formed can be brought together in a closed apparatus in an atmosphere superior in density to that at which the water has been saturated, and then thoroughly incorporated, the gas will remain in the water during the incorporation, and until such time as the dough is released from the pressure, but that directly it is released from the pressure due to such density, the gas will escape from the water, and in so doing will distend the dough into a perfect spongy mass. This, then, is the new process of bread-making."

Dr. Dauglish did not give more than an outline of the mechanical part of his process, but our readers will obtain a general knowledge of the *modus operandi* from the following description:—

"The apparatus essentially consists of a gas holder and a generator, similar in construction and principle to, but larger in size than, what are used by the makers of aërated waters; of pumps, suitable for pumping elastic fluids, and of a mixing vessel, and of a water vessel in connection, both made so that they can be tightly closed to sustain an internal pressure of from 100 to 200 lbs. on the square inch. The mixing vessel is supplied with flour through a shoot, passing from the floor above, and the water vessel with water, through a pipe from a cistern at the top of the building.

"The mixer is capable of being closed perfectly tight, and opened, by means of a proper mechanical contrivance, with the greatest facility, by one man in a few seconds.

"The order of working, and the time required for making a sack of flour of 208 lbs. into dough is as follows:—

"Opening lid of mixer and fitting within the neck the end of flour shoot, and turning water cock to fill water vessel	1 minute.
Passing from top of machine to floor above and shooting down a sack of flour	3 "
Returning, closing water cock, removing end of shoot, and closing mixer	2 "
Withdrawing atmospheric air from mixer	3 "
Pumping gas through water into mixer, &c.	10 "
Mixing	7 "
Total	26 minutes.

"At the end of which time the dough is ready to be drawn into loaves, from a nozzle or mouth, through which it is forced by the pressure within the mixer, and as it expands or rises in the act of leaving the mouth, it is ready to be baked immediately. One boy is capable of pulling the dough from one sack of flour into loaves in fifteen minutes, as fast as they can be weighed and placed in the oven.

"Thus in the short space of 26 minutes, which is subject to no variation, the baker can always rely upon having his dough ready for the oven, and this with a certainty, when the labour is well organised, which is nearly mathematical.

"Hence this process at once removes all the obstacles which have hitherto rendered a perfect system of machine bread manufacture an impossibility, which obstacles I will definitely state as follows:—

"1. The length of time (from eight to twelve hours) required by the process of fermentation to prepare dough for the oven, and the great space required for storing the masses of dough whilst undergoing the process.

"2. The uncertainty of its results, and the many vicissitudes arising from susceptibility to delicate influences.

"3. The degradation or spoiling of the flour produced by fermentation, which is equal to a money value of three to six shillings per sack.

"4. The necessity for the use of alum with poor flours, and the temptation to use it with all.

"In comparison with the above, the new process shows:—

"1. It reduces the time necessary for the preparation of the dough from eight to twelve hours to less than thirty minutes, and requires no space whatever for the storeage or keeping of dough larger than the mixers themselves.

"2. The results are absolutely certain and uniform.

"3. No sponge or degradation of flour taking place, the quality of the bread produced is equal to that made by the old process from a flour three to six shillings per sack dearer.

"4. As no change in the flour takes place, against the evils of which alum has hitherto been used, there is no gain whatever by the use of alum. Indeed, alum is absolutely prejudicial, by destroying the cohesive properties of the gluten. Even flour which is made from wheat harvested in bad weather makes a most delicious bread without any solution of alum."

We omit some observations upon the state of the baking trade in this country, as our space is limited, and pass on to the concluding portions of the paper. Various processes for the improvement of bread manufacture were noticed by the Lecturer, who named specially that of Mege-Mouries, for the utilisation of nutritious substances in the bran, which are ordinarily wasted. The chief of these is a nitrogenous body somewhat resembling glutine, but differing from it in many of its properties, which the discoverer named *cerealine*. To our mind it appears questionable if the so-called cerealine is not a modified form of diastase. Dr. Dauglish, however, treated cerealine at considerable length, being of opinion that it plays an important part during the processes of deglutition and digestion, when assisted by ptyaline and pepsine in the animal economy. As is perhaps very natural, the Doctor somewhat over estimated the advantages to be derived from the use of his bread, as according to him appetites and muscular strength will ever increase under its influence, while dyspepsia will disappear as if by magic, and speedily become a thing known only to history. Nevertheless we can bear out many of his assertions from our own experiences, as we have made a point of examining the patent bread, and find it of a light, even structure, possessing the sweet and wholesome flavour of "home-made bread" in an eminent degree, without any of that mawkishness which causes the latter so frequently to pall upon the taste.

The Chairman pointed out the points in Dr. Dauglish's paper most suitable for discussion, and

Dr. Letheby said that the opinions expressed by Dr. Dauglish were utterly opposed to the sound principles of dietetics; the mere vesiculation of flour and water was not the object in view in the formation of a loaf, and he contended that unfermented would be liable to produce gastric derangement if persevered with for any time. He considered that the use of alum in bread was still a moot question, and indeed the whole of his experiences were in direct opposition to those of the author of the paper.

Mr. Heywood and Mr. Morrison both considered the new bread more wholesome and digestible than the ordinary kind.

Dr. Waller Lewis supported the views of Dr. Dauglish, and considered that all other results beyond the vesiculation of the bread were superfluous. The new bread had met with universal favour.

Mr. Lobb differed entirely from Dr. Letheby on the action of yeast upon starch, which he denied was rendered more digestible by the former. A dyspeptic stomach was the best judge of the quality of bread, and he stated, from personal experience, that the new process gave the most wholesome results. He had not tasted fermented bread for four years, except when he did so with much pain and dyspepsia. To some, he said, fermented bread was all but poisonous.

Dr. Odling thought the concluding remark of the last speaker simply ridiculous. He considered Dr. Dauglish's equally good with the best fermented bread, but did not think the effects of alum in small quantities prejudicial. He had compared Dr. Dauglish's bread with that of Mr. Bouthron, without finding a difference of more than one or two per cent. in the amount of altered starch. He believed the temperature incurred during baking would render cerealine and diastase unavailable.

Mr. Wilson regretted that the new bread was more expensive than the common, costing 8½*d.* instead of 5*d.* or 6*d.*

Dr. Gibbon thought the bread was like distilled water, perfectly pure, but very insipid.

After some remarks by Dr. Guy, and several other gentlemen, Dr. Dauglish briefly replied upon the discussion, and the chairman then proposed the usual vote of thanks. He would not detain the meeting further at that late hour, but wished to correct an assertion of Dr. Letheby's, viz. that mankind had partaken of fermented bread from the commencement of history. That was incorrect; the larger portion of the human race fed upon unfermented bread. He thought Dr. Dauglish had made out a good case, and he (Dr. Lankester) was in favour of the new bread.

A vote of thanks was then passed to Dr. Dauglish. †

The members of the Society of Arts held their first *conversazione*, this session, on the evening of Saturday, the 28th April, at the Society's house, Adelphi. The exhibition of inventions was thrown open, where the various improvements in science and art occupied the attention of the company present. In the large room a collection of pictures by the late Sir William Ross, R.A.,[1] decorated the walls, and were greatly and deservedly admired; the smaller portraits of the various branches of our royal family, for harmony of colouring and exquisite delicacy of delineation have indeed seldom been equalled in modern times. A large number of microscopes, by Mr. Baker, of Holborn, were arranged on tables, showing many beautiful specimens of a miscellaneous character. A fine series of dissolving views, taken in Egypt, Nubia, &c. were exhibited at intervals during the evening, and afforded both interest and instruction.

Refreshments were served in the library.

NOTICES OF PATENTS.

Manufacture of Artificial Fuel. Eugene de Bassano.

Every chemist at all conversant with patent literature knows the general character of artificial fuel patents. We can only say that the one before us partakes largely of that general character. It consists in "improvements in the manufacture of artificial fuel, commonly called patent fuel, and consists in the composition of a fatty pitch, to be used in and for such manufacture; said pitch being composed of about 90 parts of the common brown resin of commerce, or other crude or waste resinous substances possessing similar properties thereto, but free from bad smell, and containing in the quantity used 90 parts of resinous basis contained in various refuse materials or matters, such as may be obtained from woollen fabrics,

[1] Now open to the public on payment of one shilling.

tallow, margaric acid, stearic acid, mineral oils, and other cheap or inferior qualities of oil, and all other bodies or matters possessing the properties, either when mixed together, or separately in themselves, of producing the largest quantity of hydrocarburate" (? hydrocarbons); "and at the same time of at least from two or three parts out of every 100 parts of matters possessing the property of perfect saponification, observing that when the above fatty matters and oils are used other than those above mentioned, but possessing the same nature thereas, but not equally saponificacious (*sic*), in such cases I vary the quantity thereof to be employed in proportion to their property of saponification and of production of hydrocarburate. I reserve to myself the right to use ordinary coal tar, or pitch, or even acid (by preference muriatic acid) in the manufacture of artificial fuel, when the proportion of hydrocarburet and saponificacious matters which they contain is such as will not cause the emission of noxious effluvia during the combustion of the fuel prepared therewith." Monsieur de Bassano probably drew up his own specification, if he did not, his patent agent might, we think, have studied English and chemistry to better advantage.

Use of Offal of Slaughtered Animals for Producing Soap. HENRY DAVIES.

THE specification of this patent is a delightful specimen of bad syntax, bad spelling, and bad chemistry. In the provisional specification the patentee uses chromate of potash and "allum" to bleach and deodorise the offal. In the final specification he employs chloride of lime as a deodoriser. The final specification is such a curiosity of patent literature, that we shall quote the first part of it, confessing our inability to judge of its merits as a manufacturing process until we see some of the soap "which are prepared according to it," as the patentee would say.

"I take the cleansed offals of slaughtered animals, and to about 60 lbs. of these offals, put into a tub, I add two gallons of clear lime water (about one pound of unslacked lime to each gallon of water)." [N.B.—Lime requires about 750 times its weight of water to dissolve it, so one pound of lime would, if pure, require about 75 gallons of water to make a clear solution.] "Also one pound of alum dissolved in hot water. The contents of the tub are well stirred for about forty minutes, until the offals are bleached, when the offals are washed in clear water, and allowed to drain for a short time. The offals are then put into a pan with about one gallon of liquid caustic soda (16 degrees), together with about one gallon of water in which one pound of chloride of lime has been dissolved, which are boiled down to a fatty matter by dry steam or a moderate fire heat; the boiling throws off the amonia (*sic*), and divests it of the impurities until it is fit for use."

Manufacture of Beer, Ale, Porter, and Spirits. PATRICK ROBERTSON.

THIS patent consists in employing a hydro-extractor to separate yeast from beer, ale, &c. The patentee also claims the separation, by this method, of wash from yeast which has been produced by the fermentation of waste from which spirit is to be distilled. He also claims the separation of wort from boiled hops by the aid of the same machine. Compare James King's patent for the separation of the solid parts of worts, wash, &c. from the liquid portion. King's patent is dated 26th July 1859, and sealed 25th January 1860, and Robertson's patent is dated 28th July 1859, and sealed 22nd November 1859. These gentlemen are not unlikely to come into collision.

Treatment of the Products of Distillation. JAMES KING.

UNDER this exceedingly vague title is comprised a patent for separating, by centrifugal force, the solid parts of worts, wash, spent wash, &c. from the liquid portion. The inventor employs for the purpose the well known machine so much used in dye works, and called a hydro-extractor. We can see numerous uses to which this machine can be applied in nitrogen up the products of the distillation of coals, shales, and native bitumens.

Preparations of Peat. W. H. BUCKLAND.

ANOTHER peat patent! Mr. Buckland's idea is to convert peat either into fuel or into cakes, which, by "cutting, carving, pressing, moulding, or embossing" may be made into useful or ornamental articles. He takes fresh peat and agitates it with water; by this means two products are obtained, one consisting chiefly of fibres, and the other the fine pulverulent decomposed portion of the peat. The watery fluid is run on to sieves, which retain the fibres and allow the powder to pass through with the water into vessels where, on repose, the suspended matters sink to the bottom. The fluid may then be run off, and the soft mass, when it has acquired sufficient solidity, can be moulded into any required form. The articles are to be dried in sheds. The patentee states that, when perfectly dry, the material obtained by this process is sufficiently hard to be turned in a lathe. This is certainly a most curious fact, and one which could scarcely have been expected. The prepared peat may also be moulded into bricks for fuel.

This patent contains more novelty than peat patents generally. We should much like to see some article prepared by the process.

CORRESPONDENCE.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

On some Antimonial Combinations.—M. Schneider[1] has found that boiling chloride of antimony dissolves the sulphide when in fine powder, and without the disengagement of sulphuretted hydrogen when the chloride is free from hydrochloric acid. Fourteen or fifteen parts of the chloride are necessary to dissolve one part of the sulphide. On cooling, the solution becomes a crystalline mass, which is seen to consist of rhomboidal prisms.

The new body is very deliquescent, and water decomposes it, with the deposit of a bright yellow powder. By heating it for a long time, it is split up into chloride of antimony, which is volatilised and the black sulphide which remains behind. Analyses have led to the formula Sb_4SCl_{11}, or $SbSCl_2.3SbCl_3$.

The preceding body, treated with an excess of absolute alcohol, produces an abundant orange-yellow amorphous precipitate, which, washed with alcohol and protected from the air, has a composition which answers to the formula $SbCl\,S_2.3\,SbS_3$. The alcohol at the same time dissolves a good deal of chloride of antimony and a little sulphide.

Weak hydrochloric acid changes the chlorosulphide after some days into sulphur which deposits, and chloride of antimony which is dissolved. Boiling concentrated hydrochloric acid decomposes it, with the disengagement of sulphuretted hydrogen.

Analogous bodies seem to be produced when acid solutions of the perchloride of antimony are precipitated by sulphuretted hydrogen.

Oxide of antimony also dissolves in the boiling chloride, and gives on cooling a grey pearly crystalline mass, which appears to be the compound $SbOCl_2.3SbCl_3$. Absolute alcohol decomposes this, producing the oxychloride $SbOCl_23SbO_3$, which is the powder of algaroth.

Bibasic Sulphate of Copper.—M. Rouher[2] says that a bibasic sulphate of copper is formed when the neutral sulphate is exposed for several hours to a dull red heat in a covered platinum crucible. It is an orange-yellow amor-

[1] *Pogg. Ann. der Phys. u. Chem.* Bd. cviii. s. 407.
[2] *Comptes-Rendus*, t. l. p. 500.

phous body. To avoid the decomposition of the bibasic sulphate, it is best to use crystals of sulphate which will only touch the sides of the crucible with a small part of their surface. Towards the end of the operation the crucible must be uncovered now and then to allow of the escape of the vapours of sulphuric acid. The bibasic sulphate is not altered in dry air, but when exposed to the free air it slowly attracts moisture, and becomes a green mass, which is a mixture of the neutral sulphate and hydrated tribasic sulphate.

Boiling water decomposes the bibasic sulphate, and converts it into 1 equivalent of neutral sulphate and 1 equivalent of tribasic sulphate, containing 2 equivalents of water.

M. Rouher has further studied the products obtained when the bibasic sulphate is added to cold water. If the two are stirred together so as to avoid any heating of the mass, and the liquid is filtered as soon as it acquires an uniform green tint, the insoluble salt formed is a trihydrated quadribasic sulphate, and the solution contains neutral sulphate. If, however, the bibasic sulphate and the water are simply placed together, a considerable elevation of temperature takes place, and the quadribasic sulphate first formed passes in part into the state of tribasic sulphate.

II. ORGANIC CHEMISTRY.

Transformation of Lactic into Propionic Acid. Lautemann[4] has succeeded in effecting this change by exposing a concentrated solution of lactic acid diluted with half its volume of water, and properly cooled, to a current of hydriodic gas. Iodine is separated, and when no more gas is absorbed the liquid is placed in a tube, sealed, and heated for some time to 140° C. The liquid then contains a good deal of free iodine. It is now filtered, neutralised with potash, and distilled with dilute sulphuric acid. The volatile product contains propionic acid, iodine, and hydriodic acid; it is agitated with an excess of carbonate of silver, and filtered boiling; on cooling the solution deposits propionate of silver.

The same transformation is effected in a much simpler manner by slightly heating aqueous lactic acid with an equal weight of iodide of phosphorus.

Action of the Galvanic Current on Lactic and Succinic Acids.—Kolbe[5] has found that lactic acid combined with potash behaves under the influence of a galvanic current just as with various oxidising agents: it decomposes into aldehyde and carbonic acid.

Succinate of soda gives at the positive pole carbonic acid and oxide of methyl.

Preparation of Iodide of Ethyl. — Lautemann[6] introduces 500 grammes of iodine and as much absolute alcohol into a large tabulated retort, and then places it in a vessel of cold water. He now adds very slowly fragments of phosphorus previously washed with alcohol. A lively effervescence accompanied with some elevation of temperature at first takes place, so that care must be taken not to add too much phosphorus at a time: but the reaction soon moderates, and enough phosphorus to make up 50 grammes can be added without inconvenience. The retort can now be adapted to the refrigerator, and placed over the fire. When the distilled product no longer becomes turbid in contact with water, it is shaken first with an alkaline solution and then with water; it is afterwards dehydrated by means of chloride of calcium and rectified.

The 500 grammes of iodine give from 562 to 574 grammes of hydriodic ether, that is from 91 to 93 per cent. Theory requires 614. The brown residuum in the retort is free from iodine.

III. ANALYTICAL CHEMISTRY.

Estimation of Phosphoric Acid by Molybdate of Ammonia. — Lipowitz points out[7] that in the method generally adopted for estimating phosphoric acid by means of molybdate of ammonia, it is rare to obtain results which agree. The molybdate, he says, even when diluted, is decomposed by the mineral acids, and consequently the precipitate contains an excess of molybdic acid. Besides this, boiling also occasions a precipitation of molybdic acid, which increases the error. It is necessary, therefore, to employ in these estimations an acidulated solution of molybdate of ammonia, which is neither precipitated on the addition of water, nor by an acid, nor on boiling. Such a solution, he says, is obtained by dissolving at a gentle heat 2 parts of pure molybdic acid, and 1 part of tartaric acid in 15 parts of water, and afterwards adding 10 parts of ammonia, sp. gr. 0·97, and 15 parts of nitric acid. The whole is heated to ebullition in a porcelain basin, whereupon about $\frac{1}{10}$th of the molybdic acid is deposited, which is separated by filtration.

In employing the above solution, the quantity of it thought necessary is placed in a capsule, and heated to boiling, and then the liquid containing the phosphoric acid is added. The precipitate is washed with water, acidulated with $\frac{1}{50}$th of nitric acid, and the filter is dried at 80° or 90° Fahr. between folds of blotting paper, or better still, over sulphuric acid.

LABORATORY MEMORANDA.

Crystals in Alcoholic Solution of Soap. — Having frequently occasion to dissolve soap in strong alcohol, I often set aside the flask in which the operation has been performed for a few days, with the cold "jelly" of soap and alcohol in it. On looking at one of these, after the lapse of a week, I was considerably astonished to find that a number of stellate bunches of crystals of a light yellow colour were forming, and that the contents of the flask were becoming liquid. I allowed the flask to remain corked and undisturbed for a few months, and repeated the experiment with other soaps, but invariably with the same result, viz. that after a day or so the crystals began to appear, but after the lapse of a month they were considerably longer and larger, and instead of a "jelly," as at first, the flask contained a liquid as thin and mobile as the alcohol itself, though slightly coloured yellow. If you, or any of your numerous readers, could furnish me with a clue to the probable composition of these crystals, you would confer a favour on—*W. L. C.*

ANSWERS TO CORRESPONDENTS.

*** In publishing letters from our correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

Yokels.—To make the chemical weather-glass you must first dissolve 2½ drams of camphor in 11 drams of rectified spirit; and then 38 grains each of nitrate of potash and sal ammoniac in 9 drams of water. Mix the two solutions and place them in a long eau de Cologne bottle or tube and carefully seal it over.

J. G. F. R.—Parrish gives the following form for a compound fluid extract of Buchu.

Take of Buchu in coarse powder 12 oz.
Alcohol . . . 3 pints
Water . . . 6 pints or q.s.

Percolate the leaves with some of the alcohol and then with the remainder mixed with the water. Evaporate the resulting liquid to 3 pints and to this add sugar 2½ lbs. Continue the heat until the sugar is dissolved, and after removing from the fire add —

Oil of Cubebs,
Oil of Juniper, of each 1 dram,
Spirit of Nitric ether, 12 fluid ounces,

previously mixed, and stir the whole together.

H. P. Leighton.—Make it into superphosphate for manure.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Detection of Iron in Presence of Chromium, by F. H. STORER.

(*Continued from* p. 254.)

SESQUIOXIDE of chromium, dissolved in dilute nitric acid, is also converted into chromic acid when the solution is boiled with peroxide of lead, with peroxide of manganese, or with a solution of permanganate of potash acidified with dilute nitric acid; minium produced the same result, though somewhat more slowly. This action is much less rapid in the cold; the sample tested with permanganate of potash contained chromic acid after having stood during twenty-four hours; the solution to which peroxide of lead had been added assumed a decided yellow colour, and afforded the reaction of chromic acid after standing three or four days; but the portion which had been mixed with black oxide of manganese gave no indication of chromic acid when examined at the end of the fifth day.

When dilute chlorhydric acid is used, instead of the sulphuric or nitric acids of the preceding experiments, similar results are obtained, at least with peroxide of manganese and with solution of chameleon mineral, both in the cold and when heated. With peroxide of lead, however, the results are less satisfactory. I have not been able to obtain any decisive indication of the formation of chromic acid in this experiment, but at the same time am not sure that minute traces of it may not have been present. The conversion of the peroxide into chloride of lead apparently interferes with the production of chromic acid.

In concentrated sulphuric acid sesquioxide of chromium is evidently slowly converted into chromic acid by the action of peroxide of lead, even in the cold, since the solution becomes yellow after standing eighteen or twenty-four hours. This action is very rapid if the mixture be heated, a fine yellow solution being obtained at once. I have, nevertheless, found it somewhat difficult to prove the presence of chromic acid in this solution, since it appears to be decomposed when diluted with water.

With peroxide of manganese, a yellowish solution is also readily obtained by boiling. In the cold, no reaction could be perceived at the end of five days.

When a solution of sesquioxide of chromium in concentrated sulphuric acid is boiled with a small quantity of chlorate of potash, chromic acid is formed. With very dilute sulphuric acid this does not at once occur, but after boiling for some time the acid becomes more concentrated, and a portion of the chromium is then oxidised. Nitrate of potash produces no similar result when used instead of the chlorate in this experiment.
